But the community is not safe! Allow me to ask, Who are the guardians of all this? Who knows whether the sites of your houses are undrained or damp; whether your cellars and basements are damp, unventilated, unclean or not? Who can tell whether your cesspools, sinks and drains are foul, untrapped, leaky or not; whether privies are overflowing, improperly located or not; if the water-closets are in proper shape; whether your yards are damp, unclean or filthy; if your water-supply from cistern or wells is bad or not; whether your meat is full of tuberculous or other disease germs; if the milk, food and water is fit to consume? Who is to say whether a man is dangerous to public safety or not; if he suffers from insanity in any of its various forms, or perhaps infectious disease, perhaps leprosy, yellow fever, cholera, small-pox? Your answer is, Oh, of course, my family doctor! Well, who is your family doctor? Is there a single sentence in our public statutes that explains the meaning in the eyes of the law of the State of the word, physician. Webster defines him as a man "who practises physic, a doctor of medicine." What does the State of Rhode Island define him to be?

The pages of history have recorded the calamitous epidemics of the past; the plague at Athens and London; the sweating sickness of mediæval times; the ravages of cholera, small-pox and yellow fever. These are not to be appeased by diplomacy alone; *applied science only* can eradicate pestilence and your cheated, maltreated, hard-laboring physicians are constantly at work to solve these great problems. There is no political power or nation in the world that cares to provoke hostilities with the United States, in spite of our defenceless coasts; but against an epidemic, gentle men, we are indeed poorly protected.

Three years ago we were in a constant dread of Asiatic cholera gaining a foothold on our continent. A popular cry at once went up: "Give us quarantine regulations so strict that the deadly enemy may be

kept out." And it was kept out, through the labors of our sanitarians and physicians.

How about the yellow fever in Florida? The State authorities were unable to cope with the grim invader, and the United States Marine-Hospital Service was called upon to assist. Had the State of Florida had a strong and well-regulated Board of Health with ample powers and appropriations, and ample quarantine protection along the coast, the fever might have been kept out, or at least restricted to one locality, instead of invading the whole State and causing losses of life and property that only time can remedy.

I can assure you, gentlemen, from personal observation, that none, among the professions in Europe is so highly respected, so jealously guarded and so amply regulated by their respective governments, as the medical profession. Over there, they aim to produce a scientific physician, not a practical practitioner only.

With this I do not mean to say, that our seats of learning should imitate Europe entirely, for there the governments control and support educational institutions and the liberal professions as well. In America, the republican spirit of our social and political institutions is opposed to centralization of that kind. But as the liberal professions are here part of the public, and so intimately connected with the people, we feel we have a right to call your attention to existing evils.

The New York *Tribune* says: "Physicians are almost the only members of the community who do not make money out of their important discoveries. It is a point of honor among them to allow the whole world to profit by their researches when they find a new remedy for widespread disease. Their reward is in the benefit which the sick and helpless receive, and in the gratitude, which should not be stinted, of the community at large."

The Minneapolis *Tribune* follows in the same line: "The greatest and best medical and surgical discoveries have been free gifts to suffering humanity the moment their value has been demonstrated. The use of anæsthetics, the principle of vaccination, new or improved operations in surgery, new drugs and methods of treatment, have invariably become the common property of the faculty from the hour of their discovery."

The Dental Law, it is generally acknowledged, has operated favorably in this State.

In concluding, I cannot help but think, that we will live to see the day when America, after having given the world the guiding example of popular government, will lead the world of science and art as it does that of politics. But this time cannot come until the people are awakened to a just appreciation of having educated and skilled members of the liberal professions, and when the private citizen shall begin to demand that a professional man shall be a gentleman and a scientist, and do all he can to aid thereto; then will America take her just place among the nations in science and art.

Medical science is of slow historical and consistent growth; even what we term superstitions, fallacies, theories, schools or sects, do not disturb the steady, onward march of medical science.

Mr. Depew, at a recent meeting of the G. A. R. Encampment here, said: "Whatever success I have had in life, whatever pleasure I have got out of life, has come from the fact, that my old Dutch father gave me a liberal education in a Yankee college. I know of no better endowment, no nobler avenue to success

than to obtain all the education that the country affords."

I respectfully ask of you, Mr. Chairman and Gentlemen of this Committee, as representatives of the Honorable Senate and the people of Rhode Island, to give your early attention to this bill before you, and do your duty to the people and the profession as upright and honorable, wide-awake and liberal-minded men, who cannot be either frightened by the howls of ignorance and deceit, or coerced by other considerations, from the duty you plainly owe to a suffering public, to do all in your power to promote the passage of this bill.<sup>2</sup>

### THE OUTCOME OF PERSONAL EXPERIENCE IN THE APPLICATION OF HYPNOTISM AND HYPNOTIC SUGGESTION.<sup>1</sup>

BY HAMILTON OSGOOD, M.D., OF BOSTON.

THERE is a popular feeling that, once hypnotized, a patient is thereafter in the control of the physician, a subject of his will, a sort of victim, as it were. This idea has arisen wholly from evil use of hallucinability, and would greatly puzzle any one of my hypnotic patients. Why? Because they know perfectly well that in the treatment there is no such thing as yielding their wills to mine. From the outset they realize that I ask nothing of the kind, that I merely request them to go to sleep, so that in that state suggestion may more easily arouse functional activity. Again, because I never attempt to learn what I might cause by any suggestion touching a patient's hallucinability. That region is never invaded. It is the suggestion of hallucinations, and nothing else which puts a patient at the mercy of the operator.

I have a patient who has stammered since childhood. He has tried every sort of treatment at home and abroad. My suggestions have been directed toward the mental part of the brain because I concluded that the muscles of speech and respiration of themselves do not stammer, but that the patient's mind does, and hence the nature of my suggestions. The result is that nothing else has ever helped my patient as this treatment is doing. That is his own assertion.

No such result could be reached in the waking state, therefore, I want the medium of sleep for my suggestions. But it never occurs to me, nor to my patient, that he is yielding his will to mine. Nor is he. For, I suggest to my patient what he requests of me. Therefore, if will be yielded, it is my will and not his, which yields.

My patients come to me for this treatment as indifferently as they would come for an application to the throat, or for electricity. They repose in perfect calmness to which, after the needed suggestions touching their ailments, I leave them for a length of time according with the nature of the case. At the expiration of that period, I repeat the suggestion and the patients awake in absolute quietude, invariably refreshed by the repose, and as fully independent of my will as if I had never seen them.

<sup>1</sup> Read before the Boston Society for Medical Improvement, January 26, 1891. Concluded from page 280.

<sup>2</sup> For draft of proposed bill see page 322 of the Journal.

The young woman whom I brought before this Society in March last, and who then showed instantaneous automatic obedience to all suggestions, is now almost wholly unsusceptible to hypnotism, and is in blooming health. This patient certainly has not become a creature of my will.

If hypnotism be "distinctly harmful" it is singular that in a prolonged daily practice of it, I have seen nothing but beneficial results and increase of vigor, mental as well as bodily.

This naturally applies to the cases which were susceptible to the treatment. A few of my patients, much to their disappointment, could not be hypnotized. In other cases the ailment did not yield to the treatment, for hypnotism will not relieve all persons. But with these few exceptions my patients have been relieved and remain so, as many letters attest. I quote one here, first saying that the gentleman enclosed a newspaper clipping which gave the inevitable and foolish assertions of Kerr as the conclusions of the British Medical Association with reference to hypnotism:

DEAR DOCTOR:—I enclose a statement of what the British Medical Association thinks of hypnotism. It is a pity that you have to be annoyed by anything of this sort.

In my own case I have to report complete cure of the trouble for which you treated me. Not a single instance of desire to use the drug has occurred during this "hay-fever" season, and there were only two days (at intervals) on which I felt "hay-fever" sensations. There has been a steady gain in weight, notwithstanding the extremely hot weather of July and August, and a general toning up of the system which is extremely gratifying.

This letter was written three months after cessation of the treatment. The case was one of cocaine habit of two years' duration, the patient having expended large sums of money upon the drug, and become a complete victim. Cocaine was used in the first instance for relief of autumnal catarrh, from the effect of which the patient was never free at any time of the year. I saw him recently, six months having elapsed. He had gained twenty pounds in weight, and had not the slightest desire for cocaine. Moreover, the catarrhal annoyances, itching and burning of the nasal passages, had not returned. In this case the patient reached only the first degree of somnolence. He was merely sleepy.

Grasset, of Paris, has said he prefers the lighter degrees of hypnotic influence, believing the suggestions are then most effective. It is these degrees which Charcot declares are not hypnotism. The case I have quoted disproves this assertion.

What other treatment could produce the same effect in a similar space of time (two weeks) in relieving a bad drug habit and protecting the patient against catarrhal misery, of which for years he had stood in such fear?

Another case was that of an aged person who has suffered during several years from rheumatic gout. The patient could not sleep without opium, and yet dreaded it. Hypnotic suggestion did but little permanently to the painful and deformed joints, but the opium having been stopped at once, suggestion gave the patient quiet nights. Suddenly discontinuing the treatment he made no difference. The nightly sleep continued.

In Mr. La Caze's case of intemperance came into my hands. The patient had drunk steadily for twenty

years, had ruined his home and kept wife and children in terror. A typical case of uncontrollable dipsomania. He readily responded to hypnotism and received five applications of suggestion on consecutive days. I was then obliged to leave town for the summer, fully expecting to resume treatment of this patient in October. The result exceeded my hopes. The patient's sister has recently called upon me to tell me that not once since I last saw him has her brother touched alcohol. His companions have vainly tried to tempt him, even sending liquor to him. But he has not only not been tempted, but expresses a positive dislike for anything alcoholic. I have just seen the patient himself. His appearance shows great gain in health. A very restless sleeper for many years, his nights are now perfectly tranquil. In reply to a question he said that once only during the past twenty years he passed six months without drinking, but that this period was one of constant daily fight with his craving for whiskey. Whereas, since last May (eight months) he has not experienced the slightest desire for alcohol.

A brother of the foregoing was an even worse case because of his excessively nervous and irritable temperament. He was sent to me as a forlorn hope. Coming at the close of a heavy debauch of twelve days he was (to use his own words) "ready to do anything for a drink of whiskey." His tremulous condition was very noticeable. After twenty minutes hypnosis, and the needed suggestion, he looked like another man; his hand was as steady as mine, and he said with great emphasis that his wish for a drink was gone. He also received five applications of suggestions. I have not seen him since, but his sister has just told me that she can hardly believe the change that has occurred in this brother who, all supposed, would not be influenced even by hypnotism. In view of such benefits as these there is not a strong appeal on behalf of hypnotic suggestion?\*

I do not propose, in this paper, to give a list of my cases, having detailed these four as examples of what hypnotic suggestion can do and what nothing else can accomplish as beneficently in the same time, if at all. On the other hand I should mention that another case of intemperance was one of the few exceptions to permanent results, which I have already mentioned. This gentleman received a prolonged treatment and went to smash again ten weeks later. It should be said, however, that his normal life is one of great unhappiness. This may have overbalanced the influence of hypnotic suggestion. Moreover, in this case there is hardly an atom of manly pluck, and the moral tissue is largely pathological in character.

Another case occurs to me which I mention because of its singularly close analogy with cases in which an impression is apt to be made upon the patient's organism, during the waking state, by the remarks of the medical attendant. Just before I saw the case in question, I was talking with a physician whose mind, it seemed to me, was not quite clear as to the meaning of the influence of suggestion upon a hypnotized person, and I asked him whether, when he discovered a serious cardiac lesion, he told the patient of it. He replied that he did not. Asking him why he did not do so, he replied: "Because of the possibly ill effect upon the patient's heart of such an announcement."

\* Six weeks later the patient called upon me to assure me that he was as free from a craving for whiskey as if he had never heard of it.

The obvious reply was: "There you have the rationale of hypnotic suggestion in a nutshell. But with this difference: If your patient were hypnotized, a suggestion would act the more strongly and directly because there would be in the patient no mental obstacles as might be the case if he were awake."

Shortly afterward I was consulted by a lady in whose pulse the sixth beat regularly intermitted, and the lady complained of sudden attacks of faintness. Hypnotizing her to the first degree, I made impressively and repeatedly the suggestions that the heart would beat with vigor and perfect regularity, and that all intermission would cease. During the next ten minutes I held the wrist and counted the pulse. After two minutes had elapsed it intermitted only at the twelfth beat. After three minutes more only the twenty-sixth beat fell out. At the end of ten minutes the pulse was decidedly stronger and perfectly regular. At the expiration of twenty minutes I aroused the patient, who expressed a sense of great relief, and of vigor she had not known for many days. Before she left my room I again consulted her pulse. It was firm, steady and perfectly regular. On the following day the new strength remained and the pulse intermitted only at the sixty-ninth beat. Suggestion again restored its regularity.

This case reminds one of Van Rentergham and Van Eeden's assertion<sup>6</sup> that "with almost only one exception, namely, surgery, we do not know of any remedy which is able to rival in its favorable results, that which we practice — hypnotic suggestion. No other remedy is capable of arousing directly the curative process. In using drugs we have to contend ourselves with placing the organism in the best conditions for the operation of the *restitutio ad integrum*."

Let it be understood that I do not use hypnotism on all my patients. I apply it in those cases in which it seems to be better and more useful than other forms of treatment, and I frequently combine suggestion with a remedy which will continue the effect of the suggestion.

I have hoped that by this time I might give personal experience in the use of suggestion as an anæsthetic, but circumstances have not provided the needed opportunity to make this use of it. Where it can thus be applied, hypnotic suggestion is naturally preferable to ether, for it disposes of the necessity of consulting the condition of the patient's heart, does not deprive him of the meal previous to the operation, and is not followed by nausea, vomiting, and the depressing sequelæ of the use of ether. There is much to be said upon this matter, but I reserve it for another occasion.

Hypnotic anæsthesia has been useful to me in examination of and applications to the uterus, in cases in which the introduction of the speculum and of the uterine probe, caused exquisite pain. In these cases the patients were wholly unconscious of suffering, and instead of leaving the chair tired, lame and uncomfortable, were rested and free from discomfort of any sort.

I have applied hypnotism in three cases of labor. I say in three cases because I attempted it in three. But in two of these labor was well advanced in one and nearly completed in the other, and I had never before seen the patients, so that hypnotism was out of the question, for, in such use of this remedy, the patient should be hypnotized at least once, and it were

better if it were done several times at different periods preceding labor. This would prepare the patient, make her familiar with the process, and thus avoid difficulty and delay in producing hypnosis, even after labor had commenced. Whereas, to attempt to hypnotize a patient unexpectedly, after the pains have appeared, would be unfair to the treatment and probably unsuccessful. The patient's mind would be too preoccupied by agitation and suffering. If, however, she have already experienced the quieting and restful effect of the hypnotic sleep, being previously possessed by the hope that it would save her all consciousness of pain, she would welcome it when labor set in.

So it was in my third case. These opportunities to use hypnotism were courteously offered me by Dr. W. L. Richardson at the Lying-in Hospital. I had seen the patient on the previous day, and found her so susceptible to hypnotism that in this case I expected an easy success.

In the waking state I prepared the patient's mind to hope for a painless labor during the hypnotic sleep, so that when I was called to her, notwithstanding she had been three hours in labor (she was a primipara) she fell asleep at a word. The suggestion was then made that the labor would continue vigorously, but that the patient would be unconscious of pain. During the two succeeding hours the pains followed each other rapidly. There were reflex effects shown in writhing and rolling about, and the patient groaned and made outcries. Between the pains I said to her: "You cannot make any sounds whatever." It was curious and interesting to observe the result. The patient rolled about and set the muscles, but did not make the slightest sound. At the end of two hours she came out of the sleep, probably because I had not suggested that it should continue. This ought to be done at brief intervals. In this case the hypnosis apparently was so profound that I did not consider further suggestion needful. On being questioned as to whether she could remember having had pain, she replied that she could not recall any sense of suffering whatever. I at once put her to sleep again, but this time the hypnosis was less profound, probably because pains had become very sharp and frequent, and I had allowed the patient to pass through one while awake. This undoubtedly preoccupied her mind when I again suggested sleep. However that may be, she woke again twenty minutes later and begged me not to put her to sleep again because she could now feel the pain, and yet could not help herself. This signified an imperfect hypnosis and I left the patient awake.

If this case had been a multipara she probably would, after the application of hypnosis, have passed through the labor without consciousness of pain. It was a tedious first labor, for four hours later the patient was still undelivered.

This instance gave satisfactory evidence of the usefulness of hypnotic suggestion during very severe pain. I am, however, inclined to agree with Gascord<sup>6</sup> of Paris, who expresses the opinion that to be actually useful in labor hypnosis must be carried to a profound degree. Even then, the suggestion of anæsthesia, the assertion that no pain will be felt must constantly be renewed.

This was done by Mesnet<sup>6</sup> in a case published in 1887. At the moment of expulsion the patient experienced pain, but on waking did not remember it and was much surprised that the affair was completed.

<sup>6</sup> Comptes Rendus.

<sup>6</sup> Comptes Rendus.

Cases, however, have been reported of women who have been delivered during a mental condition in which, although hypnotized, they were conscious of what was going on about them, but still experienced no sense of pain. In these cases suggestions that no pain would be felt during labor, had been frequently repeated previous to the confinements. This is only a proof that anaesthesia is not confined to any special stage of hypnosis, but may exist in the lighter forms of somnolence.

To turn our attention now to another topic: Having been told by a physician who was abroad during the past summer, that in Europe, as a general thing, the interest in hypnotism had nearly died out, I wrote to Professor Forel, of the University of Zürich and physician-in-chief to the Asylum for the Insane of that city, asking him if this were true. Allow me to read a translation of his reply:—

DEAR DOCTOR:—The American physician, who gave you such false information, has himself become hypnotized, that is, he is under the influence of the suggestion of the old fogies, called authorities (*die alte Zöpfe genannt Autoritäten*), whose tranquillity of mind is disturbed by everything which is new, and who, therefore, after the manner of the pope, without previous examination, have issued an *a priori* anathema against the new and perturbing researches. Otherwise, he could not assert such nonsense at a time when Moll's book upon hypnotism is celebrating the appearance of its second edition; when Bernheim is just publishing a new book upon hypnotism, suggestion and psychotherapeutics, with a mass of fresh statistics; when Wetterstrand, of Stockholm, is issuing his fine work in German, through one of our first publishers, a book filled with impressive material and careful criticism; when Scholz and I, both presidents of the first two sittings of Neurological Section of the *Deutschen Naturforscher Versammlung* in Bremen, gave such decisive results of the Nancy School of practice as easily silenced the opposition which we have experienced; when a large subscription for the aged Liébeault is being made, and when he has just issued an entirely new work; when the *Deutsche Dichtung* calls for scientific opinions upon the subject; when, also, my little work upon hypnotism is just appearing in its second German edition, and is already being translated into Russian, Polish and Swedish; when, finally, Ringier is about to publish through Lehmann, of Munich, a very scientific and statistical work upon his experience in hypnotic suggestion; and, further, Lloyd Tuckey (and many others) in England, Velandier in Sweden, Levinson and others in St. Petersburg, Van Eeden, Van Renterghem and de Yong in Holland, Freud in Vienna, Morselli in Italy, Voigt, Nouné, Sperling, Schrenck-Notzing, Munsterberg, Moll, Hirt, Dessoir and others in Germany, Ringier, Brunner and Ladame in Switzerland, Fontan, Séguard, Bérillon, Briard, Voisin, Bardon and others in France, etc., etc., have now gathered so many favorable results that doubt would cease if the majority of people were not so indolent, slow thinking and so credulous in their faith in "they say" authorities.

The charm of novelty have disappeared, but in their place have come ripened experience and statistical results. Read the books I have mentioned, and it will be clear to you, I am sure, that your wise countryman.

Search for the statement that, in general, European interest in hypnosis has ceased.

Professor Ford continues: "Injurious consequences of suggestion I have never seen, although I have hypnotized at least four hundred persons. It is only through the Charcot-Braid method of fixation of the eyes that hysterical attacks occur according to the Nancy method."

One does not any longer nowadays talk about vaccination and the theories of Darwin. They are now understood and accepted as they are. Nevertheless they are held to be correct in connection with hypnosis. It has lost the attrac-

tion of novelty, but still possesses the value of scientific truth, and will hold its place with increasing tenacity.

Yours, etc.,

A. FOREL.

In conclusion, I wish again to allude to the feeling that hypnotism is dangerous.

If it be applied with the necessary technical understanding and the proper suggestions, the causation of hallucinations being avoided, and if the patient be treated with the gentleness and consideration which is always shown a patient under any other circumstances, I distinctly deny that danger attends the use of hypnotism. I do not speak from hearsay, but from a moderately large experience. It is easy to see how harm could arise where a susceptible patient is used as a plaything for the creation of hallucinations, day in and day out, at the sweet will of medical students and of physicians indifferent to all else than their own amusement, indulgence of curiosity or a desire to watch effects.

Charcot's patients are trained, *strained* one may say, to the highest degree and by startling and exhaustive methods. It is no wonder that he sees nervous disturbance among them, and that they became mere puppets.

Charcot, therefore, declares that only hysterical subjects or persons of what he calls "a peculiar nervous make up," can be hypnotized, and that hypnotism will create hysteria. This is curiously refuted by all the statistics published by men who hypnotize according to the Nancy methods, men whose united testimony refers to hundreds of patients to Charcot's one. This is my experience, and further, while the larger number of my patients have been non-hysterical, among them strong men, those who were hysterical, and have responded to the treatment, have become free from the nervous ailment.

Is there no argument in Bernheim's decided assertion, after more than nine years of large experience, that he never has seen one case in which harm of any sort has resulted? He shows how harm could be caused, but also that it is wholly unnecessary. I can show that harm has been caused by the use of baths, but does one stop bathing? Liébeault has used hypnotic suggestion during thirty years of large practice and he pronounces its proper application harmless. It is singular that mere prejudice strikes stronger roots in some minds than simple truth.

The fact is, however, that the laity is more independent of the opinion of the physician than once was the case. People will decide for themselves, and the very results of hypnotic suggestion will be sufficient proof.

A well-known physician, who is a good hater of hypnotism, but who, of course, has not used it himself, else he would have another opinion, said to a relative of a patient whose case I have mentioned, that hypnotism was hurtful.

"Yes," was replied, "but there is my cousin, who for twenty years was constantly intemperate and now cannot be made to touch liquor, and his health has greatly improved. This was the result of hypnotism. That is proof enough for me."

Can any fair-minded man fail to see the great value of the treatment in view of such results? One can merely quietly continue the use of a remedy which, in many senses, nothing can replace, and let prejudice take care of itself.

No physician, who practically has followed the

methods of the Nancy School, confining suggestions to the functions of the organism, will admit that he has ever seen a result in any sense injurious to the patient. Consider the vast number of patients which this statement includes!

One argument against the use of hypnotism I cannot leave unmentioned. It is, that in using it a physician, simply because this thing has in the past been largely in the hands of quacks, might injure his practice or hurt his standing. This needs only one word of reply: To put it mildly; it is the argument of a man without courage. Nevertheless, the timid physician, who *believes* in hypnotism, doubtless finds reason to be thankful for the fact that to-day hypnotic suggestion stands firmly upon scientific ground, and that it is practised abroad by men whose judgment is ripe and whose medical attainments occupy the first rank.

Personally, I should feel that I were doing wrong, and were disobeying duty, if I were unwilling to apply hypnotic suggestion wherever I saw it were likely to aid the patient.

And this is the outcome of my experience in this branch of therapeutics.

### TRICUSPID STENOSIS, WITH THE REPORT OF A CASE AND SPECIMEN.<sup>1</sup>

BY FREDERICK C. SHATTUCK, M.D.

*Jackson Professor of Clinical Medicine in Harvard University, Visiting Physician to the Massachusetts General Hospital, etc.*

H. G., forty-three years old, seamstress and house-keeper, entered the House of the Good Samaritan for the first time February 19, 1886. Her father died of "liver complaint that turned to black vomit" (cirrhosis?) at forty. Her habits were markedly alcoholic for a period, but she is now a total abstainer. She had scarlet fever when eleven. In 1871 she had a cold that "settled in her legs," the muscles rather than the joints, and was laid up a fortnight. No other history suggesting rheumatism was obtained. Soon after that, she began to suffer from attacks of asthma, and could not sleep on feathers; but nothing like spasmodic asthma was ever observed by me. She could not lie on the right side on account of pain in the hepatic region. In 1878 or 1879 she went to the Out-patient Department of the City Hospital, on account of a very bad cough, and was admitted to the ward, remaining ten days. At this time she was told that her heart was affected. In May, 1881, she entered again for ten days. In July, 1881, she was delivered of a child at the Boston Lying-in Hospital, resuming work in two weeks. In 1886 the child was alive and well. In September, 1883, suffering from "bronchitis and asthma," she went to Savannah. There she became worse, and her abdomen swelled for the first time. She was treated in hospital, and relieved of her dropsy. Up to that time the catamenia had been regular, but from that date they became irregular: absent since August, 1885. In subsequent years they recurred a few times. After her return from the South in 1883 she again became dropsical, and re-entered the City Hospital for fourteen days. In the winter of 1884 she returned to the hospital; and again, for cough, in the summer of 1885. In October, 1885, the legs as well as the abdomen were swelled, and she passed three months at

the City Hospital, was transferred to St. Luke's, and returned to the City Hospital for three weeks. While at St. Luke's she became somewhat jaundiced. Ever since 1879 she has suffered from gradually increasing dyspnoea, and at times orthopnoea. Bowels have been free even to diarrhoea.

*Physical Examination.*—Slight icteric hue of the conjunctivae. General integument darkish in color. No marked cyanosis. Respiration labored. Jugulars distended. Cardiac area prominent. Marked undulation of the cardiac, epigastric and hepatic regions, beginning at the second rib at the left of the sternum. No distension of the superficial thoracic or abdominal veins. Pulsation is felt all over the cardiac, epigastric, and hepatic regions. The hand placed over the liver is raised synchronously with the apex-beat. The impulse is distinct in the fifth space outside the mammillary line. The area of cardiac dulness is somewhat increased, especially to the right. Over each of the aortic, mitral and tricuspid orifices, double murmurs are to be heard. The aortic systolic is transmitted upward into the great vessels; the diastolic downward. The systolic and pre-systolic murmurs in the tricuspid area can be differentiated from those in the mitral area, their qualities being quite different, and the tricuspid pre-systolic distinctly musical. Moderate ascites. Hepatic flatness begins at the fourth rib in the right front, and the organ can be felt through the ascitic fluid nearly as low as the navel. The size of the spleen is doubtful. The lungs are somewhat compressed by the ascent of the diaphragm, otherwise negative. The urine, 1,200 c. c. in twenty-four hours, is one of passive congestion. The girth is thirty-eight inches.

After careful study of the case I was convinced that tricuspid stenosis was present in addition to the other more obvious pathological changes.

March 7th, the abdomen was tapped with great relief. May 27th, she was discharged, free from dropsy and fairly comfortable; with a girth of thirty inches. November 27th, she re-entered, having worked only about two weeks since discharge. She was in much the same condition as at her first admission to the Samaritan, but jugular pulsation was now marked. Under treatment the dropsy disappeared, as did also the pre-systolic tricuspid murmur, and I never heard this again. The other murmurs remained much the same. May 24, 1887, she was discharged, having passed three of the intervening months at the Convalescent Branch of the Samaritan. March 15, 1888, she re-entered, having worked on a power sewing-machine up to three weeks previously, and "has felt better than for fifteen years." Orthopnoea with deficient resonance, and moist râles over both backs, especially at the bases, were noted. The other signs were much as before. No tricuspid pre-systolic murmur was heard. May 22d, she was again discharged. February 4, 1890, after an interval of nearly two years, during which she worked most of the time, she entered the Samaritan for the last time. The most marked change in the physical signs was a diminution in the size of the liver, which could still, however, be felt, and a systolic retraction in the apex region, leading to the diagnosis of adherent pericardium. In spite of treatment, including paracentesis abdominis, the use of Soutley's tubes in the legs, and leeching over the liver, the urine remained scanty, dropsy increased, and May 3d she died. The clinical diagnosis was written down as follows: mitral and tricuspid stenosis and regurgitation; aortic

<sup>1</sup> Read before the Boston Society for Medical Observation, December 1, 1890.

regurgitation and stenosis or roughening; adherent pericardium; hepatic cirrhosis; slight interstitial nephritis.

*Autopsy.* by Dr. Fitz, twenty-nine hours after death. Abdomen moderately distended. Legs and feet œdematous. Head not opened. Pericardium obliterated by old adhesions. Heart moderately enlarged. Right side distended, with differentiated clot. Aortic valve incompetent. Pulmonic valves hold water. Aortic crescents thickened, shortened, adherent to such a degree that the opening would barely admit a lead pencil. The edge of the opening showed fine white excrescences. The mitral orifice would not permit the passage of the little finger. The curtains were thickened, shortened, adherent. The auricular surfaces slightly roughened; the tendons shortened, thickened, adherent. Tricuspid orifice admits but two finger-tips; curtains and tendons shortened and thickened. Edge of curtains showed delicate vegetations. The pulmonary crescents showed delicate translucent vegetations along the line of apposition. Two of the crescents were slightly adherent. The left ventricle was not evidently hypertrophied or dilated; the left auricle dilated; the endocardium thickened. The right ventricle hypertrophied; the right auricle moderately dilated. The aorta showed extensive thick, white patches, and a circumscribed dilatation as large as a walnut at the beginning of the arch. The pulmonary artery was dilated, its inner surface showing superficial, opaque, yellow patches. The pleural cavities were obliterated by fibrous adhesions. The lungs were slightly injected and œdematous. The abdomen contained a quart of clear, yellow fluid. Spleen was reduced in size, perhaps one-third, dense, dark-colored; trabeculae distinct. Kidneys were diminished in size, dense, the capsule rather more adherent than usual; on section, of a dark-gray color. Nothing abnormal in the appearance of the bladder and the uterus. Ovaries atrophied. The liver was diminished in size, perhaps one-third, dense, the surface irregularly roughened, peritoneum thickened. On section occasional bands of fibrous tissue traversed the surface. Atrophied lobules, with pigmented central portions, were occasionally seen, especially at the periphery. The stomach showed extensive pigmentation of a bluish-slate color. The mucous membrane of the intestines, especially of the colon, was œdematous.

Pathological diagnosis: chronic adhesive pericarditis; chronic valvular endocarditis of all the valves; aneurism of the aorta; chronic adhesive pleurisy; ascites; chronic congestion of spleen and kidney; chronic interstitial hepatitis with slight nutmeg atrophy; chronic catarrhal gastritis; œdema of the intestines.

*Summary.*—A woman, long addicted to alcohol, is quite healthy in the main up to the age of thirty-five. Cough then leads to the discovery of a cardiac lesion; and during the remaining twelve years of her life she thirteen times requires hospital treatment, at first for short, later for longer periods, between times earning her support by machine-sewing by steam power. The symptoms at first are indicative of compensatory disturbance. Later, ascites and slight icterus with marked hepatic enlargement are superadded. Under treatment and rest she recovers several times from a seemingly desperate condition. For nearly two years before her death, while the subject of stenosis and regurgitation at the aortic, mitral and tricuspid orifices, hepatic cirrhosis, and probably of pleural and pericardial obliteration,

she is relatively comfortable, requires no medical advice and supports herself.

*Remarks.*—Tricuspid stenosis as an acquired lesion is of not very great rarity, is usually of rheumatic origin, affects females far more than males, is always combined with a similar condition of the mitral valve, almost always with the clear evidences of endocarditis of the aortic valves, even if this is not far enough advanced to have produced stenosis or leakage. Literature contains only one or two references to uncomplicated tricuspid stenosis. One is reported by Duroziez,<sup>2</sup> another by Torres Homem, of Rio.<sup>3</sup> Very important contributions to our knowledge of the subject have been made by Dr. Bedford Fenwick,<sup>4</sup> who collected and analyzed seventy cases. I have found nineteen other cases published since his paper appeared, which bear out in the main his conclusions, though the proportion of males is rather larger, and the average age at death less than in his cases. The diagnosis of the tricuspid lesion was made during life in less than half a dozen of the eighty-nine reported cases, and I find no American case recorded with diagnosis *intra vitam*, though I am informed that Dr. Delano of this city has twice made the diagnosis, and found it confirmed by the autopsy. It is well known that a high degree of mitral stenosis may exist without any constant murmur, to say the least. In like manner the tricuspid lesion may be silent; or, if it gives rise to a murmur, the souffle may be indistinguishable from that attributable to the mitral orifice. In my case, during a limited period of time, two distinctly pre-systolic murmurs could be heard, one at each apex, beside the diastolic souffle of aortic incompetency. Whether a pre-systolic tricuspid souffle can be heard or not, tricuspid stenosis can be pretty safely diagnosed if the patient is a female with rheumatic history, has mitral stenosis, perhaps also aortic disease, and presents the evidences of prolonged or recurrent venous stasis of greater or less degree. Fenwick explains the fact that tricuspid stenosis is so nearly confined to the female sex, more so, indeed, than mitral stenosis, as follows: In women the life work is less onerous; the action of the heart is less powerful. Back pressure is therefore slighter, and consequently the valve disturbance less than in men. In men, muscle-straining labor, greater compensatory hypertrophy, and more powerful cardiac action, prevent the inflamed edges of the valves from adhering together. (For a more complete explanation consult his article.)

The insidious character of the endocarditis in my case, seems worthy of passing mention. The attack of scarlet fever at eleven years of age may have been its origin, inasmuch as any history of the articular form of rheumatism was quite lacking. The mitral valve was probably the first to suffer. The changes in the aortic were rather higher in degree than those in the tricuspid valve, but not therefore necessarily older. The pulmonic valves were relatively slightly affected, and were probably the last to be attacked. The adhesive pleurisy and pericarditis were also insidious, and probably gradual in their progress. The patient never had any fever while she was under my observation, having a subnormal rather than an elevated temperature.

Finally, the tolerance of the patient of such wide-

spread and serious disease seems noteworthy. Cirrhosis with great enlargement of the liver, some of which was doubtless due to passive congestion, was unmistakable four years before her death.

As for the valvular lesions, their slow development probably explains in a large measure their toleration. It is remarkable that compensation should have been established with so little hypertrophy. The left ventricle was not markedly dilated or hypertrophied, although the aortic orifice was incompetent and highly stenosed. It was in the right ventricle that hypertrophy was most marked, while dilatation was most conspicuous in the right auricle.

RECENT PROGRESS IN PUBLIC HYGIENE.<sup>1</sup>

BY SAMUEL W. ABBOTT, M.D.

### VITAL STATISTICS.

THE science of vital statistics forms the basis of very much of our accurate knowledge with reference to the prevalence of disease, so far as it is affected by varying conditions of climate, geographical distribution, age, sex, occupation, and seasons of the year. Especially is this true with reference to those diseases which may be termed preventable, and which pertain to the province of public hygiene.

Dr. Loughstaff<sup>s</sup> has extracted from the Census Reports of different countries, and from the Registrar General's Returns a wealth of material which is especially valuable to the physician and to the sanitarian.

The following table is selected as showing how important and valuable material may be obtained from the wilderness of figures presented in the Returns of the Registrar General's Office:—

### RISE OR FALL IN THE DEATH-RATES.

*Per million persons living in England and Wales, from various causes or groups of causes. Averages of quinquennium 1875-1879, compared with averages of quinquennium 1850-1854.*

Rises, per million living :	
Lung diseases . . . . .	1,213
Heart diseases . . . . .	696
Brain diseases, except convulsions . . . . .	578
Kidney diseases . . . . .	222
Cancer . . . . .	191
Diphtheria and croup . . . . .	63
Typhus mesenterica . . . . .	67
Whooping cough . . . . .	45
Rheumatism . . . . .	40
Liver diseases . . . . .	35

FALLEN, per million living :		2,366
Phthisis . . . . .	694	
Developmental diseases . . . . .	617	
Fever . . . . .	605	
Dropsy . . . . .	492	
Convulsions . . . . .	344	
Cholera . . . . .	287	
Small-pox . . . . .	197	
Scarlet fever . . . . .	173	
Hydrocephalus or tubercular meningitis . . . . .	111	
Sudden death, cause unascertained . . . . .	107	
Diarrhea . . . . .	87	
Diseases of stomach and intestines . . . . .	85	
Measles . . . . .	64	
All other causes . . . . .	299	

Balance, a full of . . . . . 1,019

This table is fully discussed by Dr. Longstaff. A brief quotation indicates its value :

“ In the first place it will be noticed that six so-called ‘ zymotic diseases,’ namely fever, cholera, small-pox, scarlet-fever, diarrhoea, and measles, between them contribute a fall of 1,375 deaths per million, against which there is a set-off of 114, being the rise under the heads of diphtheria, croup, and whooping cough, leaving a net fall of 1,261 deaths per million from the principal zymotic diseases; but as the total fall from all causes is 1,049, it is evident that the deaths from non-zymotic diseases must have risen 212 per million.

"The per centage fall in the death-rate from 'fever' (chiefly typhus and typhoid) is very remarkable, being no less than 57 per cent. for each sex, the fall being spread over all ages, though old people gain most; the number of 'lives saved' is no less than 6,188 males and 6,510 females yearly; the salvage being greatest under five years of age, but very considerable at each age below 75. It seems impossible to dissociate this great saving of life from the operation of the Public Health Acts. . . . The fall in the death-rate from fever is without doubt the great triumph of the sanitary reformers. Typhus has been driven out from place after place by measures taken to check overcrowding and want of ventilation, until it now lingers only in the lowest quarters of a few large towns. Things are not perfect yet, far from it; but they were once much worse, and that not long ago. On the other hand, measures directed to improve drainage and water-supply have been most successful in restraining enteric fever within comparatively narrow limits."

*Diphtheria*.—Dr. Longstaff also presents the results of his researches as to the prevalence of diphtheria, geographically, in the different parts of England and Wales, and also for three different periods of time, 1855–60, 1861–70, and 1871–80. In general he found that the mortality of rural districts was greater than that of cities, in the following ratio, taking 1,000 as the mortality of the densely settled districts :

Mortality from diphtheria of dense districts	.	.	.	.	1,000
" " medium districts	.	.	.	.	1,178
" " sparse districts	.	.	.	.	1,507

"The practical deduction suggested by these facts is, that the cause, or causes, of diphtheria should not be sought for primarily in any higher development of civilization, such as sewers, but rather in some condition associated with a more primitive mode of life. Again, privies and ash-pits can hardly be important agents in breeding or disseminating the disease, or we should expect to find it exceptionally prevalent in those towns where such nuisances reach their worst, whereas the contrary is the case. On the other hand, low vegetable organisms developed in damp dwellings would perhaps fit in with the facts that I have brought forward, or again, some evil special to wells or other primitive sources of water-supply."

The author also suggests that the comparative pathology of the domestic animals affords a suggestive field for research, with reference to the greater prevalence of diphtheria in the rural districts.

In the Statistical Reports of the Italian Government<sup>9</sup> are to be found many admirable summaries of the comparative prevalence of disease in different countries, from which the following table is condensed:

PREVENTION OF DIPHTHERIA.<sup>10</sup>

One of the practical results of the investigations of Roux and Yersin of one hundred cases of diphtheria is the diagnosis of mild cases of the disease, to which the attending physician is so often inclined to attach the names of "diphtheritic sore throat," "tonsilitis," "sore throat," etc. Even if the medical attendant at first pronounces a case to be diphtheria, he renounces his view if the affection rapidly disappears. "Yet these slight sore throats are sometimes the starting-points of severe epidemics of diphtheria. The diagnosis of these apparently benign diphtherias can only be established by the microscopic examination of the false membranes and by cultivation on serum. We observed forty-seven diphtheritic children who recovered. Some were seriously ill, others slightly. We were enabled to study all the degrees of the disease from those which were recognized at first sight to those which might pass unrecognized. In every case sowing on serum gave specific colonies. Whether the origin of these colonies were from a severe or from a mild case, they had the same characters, and the microscopic appearance of the bacilli was the same. From the appearance of the colonies and the form of the bacilli, all the cases contained the same organism, all had the same right to be called diphtheritic. Yet what a difference between the serious nature of the one, and the benign nature of the others."

ABSINTHISM.<sup>11</sup>

In an address before the French Academy of Medicine, Dr. Lancereaux calls attention to the general use in France of absinthe, and other strong liquors containing essential oils, as one of the causes of the depopulation of the country. He lays special stress upon the disorders caused by absinthe, and similar liquors, as being chiefly those of the nervous system, the senses, the locomotive organs and the intellect, all being impaired. Dr. Lancereaux appeals to the Academy to exert its influence to diminish this public danger.

"All of the liquors containing essential oils are injurious to health, and often produce fatal results. The mortality from them is very great, and greater than might at first appear, since the victims of the habit are destroyed not only by the primary poisonous effects, but by later chronic diseases resulting therefrom."

Dr. Lancereaux suggests, as remedies for this evil, which menaces the nation, a limitation of the sale of spirits, a supervision of licenses especially as to the moral character of the applicants, and finally a tax on all liquors containing essential oils, which, as he says, are luxuries, always injurious, and never useful.

EXAMINATION FOR THE DIPLOMA IN PUBLIC HEALTH AT CAMBRIDGE, ENG.<sup>12</sup>

The following list comprises most of the questions put at an examination for the Diploma in Public

<sup>10</sup> Journal d'Hygiene, January 8, 1891, p. 16.<sup>11</sup> Public Health, November, 1890, p. 209.

Health, at an examination in October, 1890. There were 57 candidates, of whom 41 were successful. Three hours were allowed for six questions:

- (1) In what respects as to the kind and quantities of its constituents does "ground-air" differ from ordinary atmosphere air, and how is it affected by the movements of the atmosphere, and of the water in the soil?
- (2) What is meant by the terms, "temporary hardness," "permanent hardness," and "total hardness" as applied to water, and to what substances are these forms of hardness respectively attributable? What degree of hardness would entitle a water to be termed "hard"? By what means may hard waters be softened? Explain exactly what takes place during the process of softening?
- (3) Under what heads may food-substances be classified? What is the average chemical composition of those of each class? State the amount of each required in the average dietary of a man.
- (4) What dangers to health are attendant upon the use of gas-stoves for heating dwelling-rooms, and how may they be best obviated?
- (5) State the proportions of the chief constituents of average sewage from a water-closeted town. How does such sewage differ from that of a town without water-closets? What is the theoretical annual pecuniary value of the excreta of an average adult, and how has this value been estimated?
- (6) Sketch and describe a good form of hopper-closet and its connection with a house drain. What are the advantages of this form of closet? How should it be supplied with water?
- (7) Describe one method of estimating the amount of nitric acid in a sample of water. Of what importance is this determination?
- (8) Upon what principles does natural ventilation depend? Explain Montgolfier's formula. How far can it be relied on?
- (9) Discuss the value of gelatine as a food-substance.
- (10) What are the properties of ozone? How is its presence in the air ascertained?
- (11) How much work expressed in foot-tons may be expected from a man who has a diet of twelve ounces of cooked beef, thirty ounces of bread, two ounces of butter, and seventy ounces of water in twenty-four hours?
- (12) How are death-rates calculated? If the population and death-rates of two districts are known, how can you calculate the death-rate of the combined district? If the population of one district is 21,575 and the death-rate 18 per 1,000 annually, and that of another 20,824 with a death-rate of 20, what is the death-rate of the combined district?
- (13) What is the evidence as to the relation of vaccination marks to: (a) Attacks from small-pox; (b) Deaths from small-pox?
- (14) What is the incubation period of small-pox and vaccinia respectively? How would your knowledge in this respect influence your practice when persons unprotected, or not fully protected by primary vaccination, are exposed to the infection of small-pox?
- (15) Give a short account of the diseases which have been known to result from eating the flesh of the pig.
- (16) Are you of the opinion that a running stream of water which has become unfit for drinking purposes, on account of the admission of town sewage into it, may, after a flow of some miles, again become fit for drinking, and that it may be safely used as an ordinary town supply? Give the reasons for your opinion *pro* or *contra*.
- (17) What do you consider to be the best method of disinfecting woolen materials after exposure to contamination by small-pox? What practical objection has been urged against the employment of dry heat for the purpose of disinfection?
- (18) A member of a family of school children is attacked by scarlet fever. The patient is nursed at home, although the house is too small to allow of satisfactory isolation, and, therefore, the other children are temporarily forbidden to attend the day-school. For what period, after the complete recovery of the patient, the disinfection of the house, etc., would you consider it necessary to keep his brothers away from school? State the reasons for your answer.

STATE UNIFORM OF FRENCH DOCTORS OF MEDICINE.—By a clause in a law bearing the date of the 20 brumaire, an XII, otherwise November 12, 1803, it is enacted that a plain Doctor of Medicine is authorized to wear at public ceremonies, or when giving evidence before a court of justice, a costume thus composed: a black gown of bolting cloth, the back and front of which are of crimson silk bordered with ermine; a black coat; cambric hands, and a cap of crimson silk with a border of gold lace.

## Clinical Department.

### TWO CASES OF DIPHTHERIA.<sup>1</sup>

BY F. E. BUNDY, M.D., BOSTON.

On the evening of Friday, September 5, 1890, I was called to the house of a neighbor, Mr. B., to see one of the children, who was feeling ill. I found that the family had returned the day before from Strawberry Hill, where they had spent two summers in a hired cottage. The family consisted of Mr. and Mrs. B. a sister of Mrs. B. and six children.

One of the boys, David, four years old, had been ill for about twenty-four hours, had been hot and feverish, had complained of bad feelings in his stomach, and when asleep and just after waking was inclined to delirium. As the children had been playing in the back yard, where there were pear trees and a grape vine, with fruit not fully ripe I readily adopted the suggestion of the mother, that the boy's indisposition was the result of the forbidden fruit, and no anxiety was felt. The next morning David was better and my attention was directed to his older brother Peter, who was complaining very much as his brother did the evening before, but with milder symptoms. The same treatment was advised.

Sunday morning I was sent for in haste. There were indications of something more serious than indigestion in both boys. In Peter's throat there was but little swelling or inflammation, but both tonsils were covered with a thin diphtheritic membrane. It was impossible to get a satisfactory view of David's throat, but there was no question then nor afterwards as to the diagnosis. The tonsils were so swollen as to fill the passage, the mucous membrane, within view, was covered with a thick white exudate, around and beneath which the surface was very highly congested, while from between the enlarged glands there welled up a quantity of mucopurulent matter.

At my suggestion the four well children with their aunt were immediately removed to the house of a relative in another part of the city, and all intercourse between the two houses forbidden. The services of a competent nurse were obtained, and as far as possible the rooms to be occupied by the patients, were cleared of unnecessary furniture and draperies.

Peter had never been a strong boy, he had had several attacks of bronchitis, the last a year ago, but during this attack his symptoms never became alarming, there was but little enlargement of the cervical glands, the nasal surfaces were not implicated, and there was an absence of that intense engorgement of the throat so often seen. The case progressed favorably, the temperature gradually became normal, until Thursday morning, when the nurse called my attention to the fact, that the respiration was a little hurried and to some coarse mucus rales, which were heard at the bottom of each lung, back and front. The temperature had risen from normal to 103° (at noon of the same day it was 101°), and it was very evident that something serious had or was about to happen. I learned that in the night he had refused to use the chamber for an evacuation of his bowels, and had insisted on being carried to the bath-room, where he had been allowed to remain several minutes.

On the next day, Friday, my fears as to any lung

<sup>1</sup> Read before the Boston Society for Medical Observation, December 1, 1890.

complication were allayed and the high temperature of the day before accounted for by the appearance on the face, arms and chest of a thick scarlatinous eruption.

From this date Peter made an uninterrupted and uneventful recovery. The albumen which had been symptomatic of diphtheria disappeared a day or two before the appearance of the eruption, to reappear later as one of the sequelæ of scarlet fever.

The other boy, David, was not as fortunate as his older brother. From the start his symptoms were more grave than Peter's. A bloody discharge from the nose, appearing almost simultaneously with the exudate in the throat, the early swelling of the cervical and submaxillary glands, the peculiar pallor of the surface, all indicated a primary systemic infection. On Thursday, the seventh day of the disease, albumen was found in his urine which never entirely disappeared. Energetic treatment, which will be mentioned later, was adopted and a liberal supply of nourishment and stimulants given. The boy was so abominably obstinate, that for several days he took nothing except as he was compelled to do so by force.

By Friday, the eighth day, there seemed to be a slight improvement, and on Sunday the progress was so marked as to raise great hopes of his recovery. The swelling of the glands was much lessened; less force was necessary to compel the taking of nourishment and sleep was natural and restful. On Tuesday I found him playing with his toys, and I was led to make the same mistake, which I presume many, wiser than I, have made. I congratulated myself and an anxious family, on the fact that the worst was over, and that in a few days he would be quite well again. By Wednesday the throat was quite clear of membrane and looked fairly healthy, and considerable nourishment was taken with apparent relish.

Thursday morning, I was told that the boy had rejected some of his food. I made some change in his diet and ordered a little pepsin, but felt no alarm. Thursday evening the father came over to tell me that the boy still vomited occasionally. As for the last ten days we had been rather crowding his stomach with food, I thought that the over-worked organ was rebelling against such treatment, and decided to give it a partial rest until morning. Friday morning, the refusal of the stomach to retain even a little brandy and water, the deathly pallor of the surface, which had come on during the night, and an exceedingly weak pulse, banished all our hopes of recovery, and in spite of all that was done, including a consultation with Dr. Whittier, the patient died at two o'clock Saturday morning, a typical case of cardiac paralysis following diphtheria. There was no loss of consciousness and to the last struggle there was evidence of considerable physical strength.

Some mention should be made of two of the four children, who were sent from home when the nature of the disease was first discovered. I visited them the next day, Monday, when, with the exception of one, a girl of fourteen, they were in their usual good health. This girl, while making no complaint of feeling ill, had a temperature of 102°, which the next day was reduced to 101° and on Wednesday was normal. At my visit Wednesday morning, I found a boy of eleven complaining of a bad headache and sore throat. There was a slight redness of the fauces and a temperature of 101°, on account of which I separated him from the other children. Thursday his temperature was 102°

with less headache and but little sore throat. On Friday he was better, and on Saturday, so well that he was allowed to associate with the other children and like the others to omit all medicine, with the exception of an occasional dose of iron.

In regard to the treatment of these cases, as soon as the diagnosis of diphtheria was made, I adopted that which has been very highly recommended by many who have had a large experience in this disease. I gave to each of the boys, Peter and David, one-thirtieth of a grain of bichloride of mercury once an hour when awake, for twenty-four hours, then once in two hours and later in the disease every three or four hours. It was discontinued on the fifth and sixth days. For four days, three times a day, I made an application to the throat of sulpho-calcine and attempted to use a spray of the same. I gave small doses of antipyrin for fever and restlessness, and later Dover's powder to procure sleep. I had a canopy built over a cot-bed into which, after the children were asleep, steam was introduced; and a warm flaxseed poultice, frequently changed, to reduce the swelling in the glands of the neck. I gave tincture of iron continually from the second day, and insisted on all the nourishment, in the shape of milk, egg-nog and beef-juce, that the little fellows could be made to swallow. To the children sent from home and old enough to gargle, I gave a solution of liquor sodæ chloratæ or of boric acid, and to each liberal doses of tincture of iron and an abundance of nourishing food.

In a similar case I would not again insist on local treatment when force was necessary in order to accomplish it. With these children the operation required the assistance of the father, the nurse and often the grandmother. With a child kicking and squirming and with only an occasional glimpse at the throat, the application cannot be made with any nicety and there is danger of wounding healthy tissue and so making a new surface for the deposit of the pseudo-membrane. I doubt if anything is gained by forcibly removing the exudate, when it does not seriously impede respiration, as it immediately returns unless the disease has begun to abate. If the disease is systemic before it is local, in favor of which there is a large amount of evidence, very little, if anything, is accomplished by local asepis when procured at the expense of the strength lost in the struggle.

I would make an application of some astringent or antiseptic, or better still by means of the spray, when it can be done without exciting opposition or alarm. I don't think that I would be again deceived by the danger signal of vomiting during the apparent convalescence from diphtheria, and yet, I believe it to be true, as I told the father of these boys, that if we had known from the beginning what the result in the case of David might be, we could have done nothing successfully to avoid the fatal issue.

Whatever the specific poison or organism may be, that causes diphtheria, it had associated with it, in the cases above cited, at least one other poison, that of scarlet fever. There seems to be a close relationship existing between diphtheria and scarlet fever, they often dwell together in the same subject and resemble each other in symptoms and method of attack more perhaps than any other two diseases. The period of incubation in both varies from two to eight days; the type in either may be mild or malignant, an eruption sometimes occurs in diphtheria and an exudation in

scarlet fever, in each the favorite seats of attack are the throat and nose and frequently nephritis occurs as one of the sequelae or in both diseases. From these and other resemblances it is not strange that some observers have regarded the two as identical and the particular manifestation as depending on the soil in which the seeds are sown.

It may be interesting to know something of the locality where this family lived during the summer. They occupied one of three cottages built near together on the beach at Strawberry Hill. The privy, built over a vault, was but a few steps from the kitchen door and was at times very offensive. Two weeks before the family left the house they were visited by the Board of Health from Hull, who ordered a trap to be put under the kitchen sink, from which they detected foul odors. The drinking-water which was not very palatable, came from a reservoir at some distance from the house.

There was one circumstance which worked very much to the disadvantage of all the parties interested in these cases, and which, among other things, accounts for the fact that but little reference is made to temperature and pulse in this report. The father, who was devotedly fond of his children, had been exceedingly indulgent with them, and their way had always been his way; so that when it came to requiring of them that which was disagreeable, there was open war. Only when I was present could they be induced to take the simplest nourishment, without a fight. Coaxing, threats, bribes, even to the promise of the doctor's horse and buggy for their own, and the most outrageous and needless lying, gave out early in the siege, and no resort was left save physical force.

### RABIES.

BY F. W. JOHNSON, M.D.

As cases of rabies are occurring from time to time, the report of the following may be of service in assisting to do what is necessary and in giving the proper advice to friends and patients.

October 24, 1890, I was consulted by Mr. X., concerning his eight-year-old son who had been bitten on the upper lip by a pet pug bitch. The bitch was in heat and her strange actions for several days had been attributed to her condition. Four days previously, after being provoked, she had snapped at the boy, striking him with her upper front teeth as described above, and inflicting a wound sufficiently deep to bring blood. A few minutes later she grabbed the hand of the boy's playmate but did not bring blood.

The next day she became snappish, biting at several members of the family. She had lost all appetite for food, but picked up and eat everything she found on the floor. She roamed about the house as if in search of something, tearing the rugs and eating the ravelings. Thirst was unquenchable, eyes were sunken, pupils dilated, tongue was protruded and dry, and lower jaw dropped. Alarmed at her condition her master took her to the Village Street Hospital, where she died in thirty-six hours.

Professor Lyman, of the Veterinary School, thought that she had died of rabies. He writes: "My own observation of the case was quite limited, as I had no knowledge of any special interest attaching. First

saw her Wednesday morning, October 22d. She was lying in a corner of the box, with mouth open, tongue protruding and discolored, under jaw dropped, eyes partially closed, and sunken. On making a sudden noise, as a kicking on the box door, she would come forward exhibiting considerable excitement, biting at the door, etc. If a stick were put within her reach she would bite at it, furiously for her strength. After a little of this she would go to a corner and lie down, as if utterly exhausted. In the afternoon these symptoms were present, but in a very much less degree—there was very much less strength. On Thursday I saw her at about 9 A. M., she was almost dead, unconscious, with cold extremities and body surface. She soon died."

The first time the bitch came in heat she was lined and gave birth to three puppies. June last she was again in heat and was sent into the country, but was not lined. During this heat she seemed at times in great pain and acted in a very strange manner, alarming those who had charge of her.

The body was sent to the Harvard Medical School, where Dr. Ernst kindly inoculated some rabbits. I received word from Dr. Ernst, November 11th, that the rabbits were dying and that the diagnosis of rabies was confirmed. I saw one of the rabbits. He was almost completely paralyzed, the paralysis having begun, as is usual in such cases, in the hind legs.

It was decided that the boy be sent at once to New York to Dr. Gibier for treatment. The mother, father and boy started for New York thirty-six hours after the bitch died and four days after the bite was inflicted. The boy reached New York Friday night, and Saturday morning was taken to Dr. Gibier's Clinic. That day six subcutaneous injections of the fluid were made, two at each sitting, one on either side of the abdomen. Then for thirteen days two injections each day were made in the skin covering the abdomen.

No reaction followed the injections, and except the slight soreness at the point of puncture the boy was perfectly comfortable. The boy has remained perfectly well up to the present time.

### Reports of Societies.

#### BOSTON SOCIETY FOR MEDICAL OBSERVATION.

T. F. SHERMAN, M.D., SECRETARY.

REGULAR Meeting, Monday evening, December 1, 1890, Dr. C. F. Folsom in the chair.

Dr. F. E. BUNDY reported

#### TWO CASES OF DIPHTHERIA.<sup>1</sup>

Dr. E. M. BUCKINGHAM: The fatal ending of one of these cases after it had appeared to be doing well is simply an example of what we all occasionally meet with, and reminds us how very guarded the prognosis should be in diphtheria throughout the whole course of the disease. I understood Dr. Bundy to speak unfavorably of swabbing as a local application as compared with others—spray for example. I agree with him in this, thinking that a spray or gargle is more agreeable to the patient, equally efficient and perhaps less capable of doing harm. Where there is

<sup>1</sup> See page 311 of the Journal.

any great amount of sloughing, disinfestation of some sort is, I think, exceedingly important. If, however, the child resists it, then the extent to which we should persist becomes for the individual case a matter for very delicate judgment.

DR. BROUGHTON: The class of cases that refuse treatment seems to me to be the most difficult and unpleasant to manage. I have seen a few. I had one little fellow who went through a very similar process of resistance to all treatment, and ultimately died. It was impossible to remove the case to the hospital on account of the refusal of the family. On one occasion the little boy ran down stairs to the cellar to escape his mother who wished to give him milk. He took absolutely nothing for two or three days except water. The only thing that could be done in that case was to fill the room with the vapor of turpentine which possibly accomplished some good.

My personal experience with the use of turpentine has been limited. I have heard men who have used it much more than I speak of it as only one of the many things that might be used. Thus far I have been favorably impressed with its use locally by the direct application to the patch.

In regard to cardiac failure, Dr. Bundy speaks of its approach being shown by signs of vomiting and other symptoms. In one case which I have seen, a little girl who had been doing very well, death was almost instantaneous. There were no symptoms observed by anybody indicating the possible approach of the trouble, and my feeling has been that it is not at all uncommon for these fatal cases of heart complication to occur without anything to guide a practitioner as to their onset.

DR. F. C. SHATTUCK: Last year Dr. Garland gave me a suggestion which I have used in two cases. I do not see many cases of diphtheria, I am happy to say. In those two cases I used tablet triturates containing one one-thousandth grain of corrosive sublimate each. The patient takes one every ten minutes, which keeps up a very slight local action. Dr. Garland tells me he has seen very offensive throats sweetened rapidly under its influence. There is no taste and children are perfectly ready to take them.

DR. C. P. PUTNAM: I should agree with the gentlemen who have already spoken against trying to swab out the throat by main force. The fight that may follow is exhausting, and I do not think it pays; but very often children may be got to swallow things, and the suggestion Dr. Shattuck has made I think is an excellent one. Very often young people with sore throats will swallow a saturated solution of salicylic acid in large quantities. One-half drachm of salicylic acid to the quart of boiling water will make very nearly a saturated solution. A constant stream of that running over the affected part has a marked effect in diminishing the fever. Of course in many cases of diphtheria, children and grown people will not swallow at all because of the pain. But while it is often very difficult to cleanse the throat in any way, practically impossible, the nasal cavity can always be washed. It requires but a moment of struggling and one that does not fatigue the child much to throw a stream of water into one nostril. If there is a clear passage round, it comes out through the other again. This is advantageous for more than one reason. In the first place the nasal mucous membrane is very delicate and very likely to absorb poisonous material,

and therefore it is rather more important than the fauces. Besides that I think it is very important that air should pass through the nose, and there are many cases in which after a little washing the nasal cavity becomes clear and the respiration goes on as it ought to through the nostrils. It is necessary to have some one help douche the nose. The patient has to be held a moment with the arms at the side, and by standing behind the patient with your two wrists you can hold the head against your body and without any great difficulty can squeeze from a bulb syringe a jet into one nostril, and then into the other. When there is much swelling and much membrane around the back of the palate, the posterior nares cannot be closed, and the water will run down into the pharynx, but it goes down into the œsophagus rather than into the trachea. I do not think there is any practical danger in carrying out the procedure.

DR. VICKERY: I know of a case where a similar treatment was adopted, and the patient recovered to suffer from otitis media which the aurist ascribed to the treatment. I believe most fully in the desirability of cleansing the nose, but should like to inquire if any other gentleman has ever heard or experienced similar results from the carrying of anything into the Eustachian tube, and how it could be avoided. Certainly in this case it caused a good deal of unpleasantness.

DR. BECKINGHAM: I think it is an accident that has happened a number of times where the douche has been a very large one, and that the only way you can avoid it is by using a very fine spray.

DR. FOLSOM: A very large number of cases of diphtheria are treated at the City Hospital every year now, and the almost universal treatment is to spray the throat with a rather large atomiser. I think the danger from otitis media is regarded as being very small. It is very surprising to see how quickly the adroit nurse gets on with even the most difficult children, and certainly there are probably no more difficult children to manage than we have there, and the spray is rather grateful. I do not remember bichloride having been given internally at all. In fact we give very little medicine excepting tonics and such as build up the strength. In a large proportion of cases nutrient enemata have been given from the beginning of the disease, and it is often quite essential where the exudation is very large or the throat very much swollen, and it is impossible to get the patient to swallow enough.

With regard to paralysis of the heart it seems to me that the evidence so far is that it may be due to neuritis involving the pneumogastric nerve, and of course in that case the only thing to do is to keep children quiet in bed as long as possible, and to have a battery at hand for the nurse to use in case of emergency. I do not know that any autopsies have verified that fact in diphtheritic heart-failure, but they have verified it repeatedly in heart-failure due to alcoholism and alcoholic neuritis. In a very large proportion of the cases with a very weak pulse in diphtheria there may be found evidence of peripheral neuritis in the arms and legs, for instance.

In conclusion, Dr. C. P. PUTNAM thought the dangers of douching the nose not so great as was commonly believed. In fact such injuries to the ear are generally known only by hearsay, except to aurists who collect their patients from a very wide field. In diphtheria the middle ear is often inflamed more or

less without any douching. It is unfair to attribute the inflammation to douching whenever the douche is used, and a great many cases would be required to prove that the coexistence of inflammation with douching was more than a coincidence. He thought spraying much less efficient.

DR. F. C. SHATTUCK read a paper on

TRICUSPID STENOSIS: WITH THE REPORT OF A CASE, AND SPECIMEN.<sup>2</sup>

DR. F. MINOT: I cannot say from my own observation that I have ever seen a case of undoubted tricuspid stenosis, at least undoubted in my own mind. The three important signs I presume would be: the existence of a systolic murmur in the tricuspid region, the signs of dilatation of the right auricle, and the systemic engorgement. These all appear to have been evident in this case, and they are also evident—at least as far as the systematic engorgement goes—in so many other cases of cardiac obstructive disease that I suppose the diagnosis must mainly rest upon the direct murmur at the tricuspid orifice, and that is generally so very slight as hardly to attract attention unless sought for very carefully. In a case like this where there was such a complication of cardiac troubles it is certainly very remarkable that the diagnosis should have been made so accurately and successfully.

DR. FITZ: I can only give my testimony with regard to Dr. Shattuck's enthusiasm in this case, and to the successful results in confirmation of his diagnosis. The case is remarkable for the severity of the lesions, lasting for so long a time with so much suffering during the continuance of the attack of cardiac weakness. If the disease of the pulmonary orifice had existed at the time Dr. Shattuck's examination was made he would probably have added this to his list of lesions. As I remember, the diseased appearances at that valve indicated a much more recent condition than at the other valve orifices. I have nothing to add except to compliment Dr. Shattuck on his skill in regard to his diagnosis.

THE NEW YORK NEUROLOGICAL SOCIETY.

MEETING of February 10, 1891.

The President, DR. LANDON CARTER GRAY, in the chair.

THE USE OF ATROPIA IN TREATMENT OF LOCALIZED MUSCULAR SPASM.

DR. W. M. LESZYNSKY read a paper with this title. The speaker had, in March, 1884, reported a case of clonic torticollis, successfully treated by the subcutaneous administration of the sulphate of atropine. The first case of the present series was that of a man, thirty-seven years of age, who had, three years previously, muscular spasm, beginning at the right side of the neck, which had come on six weeks after an abscess had been opened at the angle of the jaw on the right side. The force of the spasm was increased by mastication and closure of the jaw, and it was more active upon mental excitement. He was frequently aroused from sleep by the severity of the paroxysm. There was no complaint of pain, but only of numbness in the right lower lip. He was treated by means of

medicine and electricity for four months without relief. There was well pronounced clonic-tonic spasm affecting the right platysma, forcibly drawing downwards the facia about the chin and the lower angle of the mouth. The clonic character of the spasm preponderated, and was almost constant. The muscle was hypertrophied to nearly four times its normal size, and its outline was distinct and well defined. There was an area of complete anaesthesia one and one-half by three centimetres at the vermilion border of the lower lip near the angle of the mouth on the right side, which extended inward over the mucous membrane and over the alveolar process of the lower jaw. The mechanical irritability of the facial muscles was well marked. The jaw-jerk was demonstrable. There was no apparent caries of the teeth. There was no abnormality evident in other portions of the body.

The treatment was commenced by the application of a cantharides plaster over the affected muscle. After one week had elapsed an injection of  $\frac{1}{150}$  of a grain of sulphate of atropine was made into the platysma. For the next three days an injection of  $\frac{1}{100}$  of a grain was given, when the exaggerated mechanical irritability of the facial muscles had markedly diminished, and there was an abatement in the frequency of the spasm. Sensation was also returning in the anaesthetic area. The dose of atropine was gradually increased, until  $\frac{1}{45}$  of a grain was given daily. At the end of two weeks the most energetic effort by pressure and otherwise, had failed to produce any spasmodic action in the platysma. The administration of the atropine was then discontinued. Report from the patient a month later was that there had been no return of the spasm. The solution used was one grain atropine sulphate, to one ounce distilled water. One minim of this solution represented  $\frac{1}{450}$  of a grain of atropine. The speaker's method had been to give four minims at the first injection, and to be on the alert for constitutional effects. Upon discovering that there was no idiosyncrasy in regard to the drug, it was administered once daily and the quantity gradually increased from day to day, until the desired effect was produced or intolerance was established. The production of severe constitutional symptoms was not an essential feature in this plan of treatment. One of the experimental physiological effects of the drug, when given in sufficient quantity, was to paralyze the motor nerves, first affecting the trunk.

DR. V. P. GIMNEY, on being asked for his views on the subject of the paper, said he did not know whether the author had included in his earlier reports cases of hysterical torticollis, rotary spasm, and so on. He doubted whether it was the intention to include that class of cases known as spastic paraplegias. The cases which came under his personal observation were only those of functional disturbance or deformity.

THE DEGENERATIVE DISEASES OF THE SPINAL CORD, WITH A DESCRIPTION OF A NEW TYPE.

This was the subject of a paper by Dr. C. L. Dana. He said that almost all of the organic diseases of the spinal cord which the physician had to treat belonged to one of two great classes, the destructive, or the inflammatory. There might be some doubt felt as to the class in which the case the speaker was to report should be placed. He therefore preceded the history of his case, with some remarks upon the pathology of

<sup>2</sup> See page 307 of the Journal.

the inflammatory and degenerative processes which affected the cord. Softening and degeneration of the cord were both processes that had to do essentially with the nerve parenchyma, the cells and fibres. They were always associated with a good deal of vascular activity, and connective tissue proliferation, eventuating in cicatrices and scleroses. The results of bacteriological work had given us a wider grouping of these diseases, and a more certain knowledge of the nature of inflammation, a practical application of which seemed now to be in order. According to modern doctrine inflammation was the reaction of the organism to an irritant; this irritant was practically always a microbic poison. Without a microbe there could be no inflammation. Again, inflammation was an attempt to eliminate the poison or irritant, and then to repair its ravages. Still further, inflammation had to do with blood-vessels and connective tissue only. Many cases of so-called chronic myelitis were injury, either the result of an acute destructive process, or due to a nutrition disturbance which was of vascular origin, such as obliterating arteritis. Finally, it seemed to the speaker that the terms transverse myelitis, compression myelitis, and acute myelitis might as well be dropped from ordinary use, unless there was a distinct evidence of septic infection. The true anatomical tests of inflammation should be based upon studies of true myelitis produced by the introduction of pyogenic organisms.

Turning again to the subject of the degenerative disorders of the cord, those of primary degenerations were the ones dealt with. They were, so far as now known, locomotor ataxia, lateral sclerosis, the combined scleroses, multiple sclerosis, periependicular sclerosis, and the progressive muscular atrophies, including amyotrophic lateral sclerosis. The primary degenerative diseases of the spinal cord had all a certain degree of kinship. The course of all was uniformly progressive, and one not very infrequently complicated another. The sharpest distinctions were found between those affecting the gray matter and those affecting the white. The degenerations of the white matter were more common, slower in course, different in etiology and much more varied in symptomatology, than those of the gray. As a rule, the gray matter was not much involved except secondarily and late. The differentiation of the disease under consideration from other degenerative diseases, and the placing of it in a separate group, was justified by the following observations: Etiologically it was peculiar, in occurring so often in women and at comparatively advanced periods of life. Syphilis did not appear often to be a factor in its cause. Symptomologically it was distinguished by its almost subacute course, by the presence of paræsthesia and often of anesthesia, with, as a rule, spastic symptoms, and finally paraplegia. Pain also was not common. Ataxic paraplegia, on the other hand, ran a very chronic course, anesthesia was quite rare, and paraplegia came late. Anatomically it was peculiar, in the fact that degenerative processes were rapid, and accompanied with a peculiar collateral or terminal softening. The lesion was also less diffuse than in ataxic paraplegia, and involved the root-zones of the posterior column and the posterior columns generally, more than in the allied disease. Its distinction from locomotor ataxia, with secondary lateral sclerosis, was in every way most marked.

The history of a case was related. The patient was a woman forty-four years of age, who, on admission to

the hospital, could barely walk with assistance. The legs and thighs were considerably wasted, the left more than the right. They were slightly drawn up, and she suffered at times from painful contractures in them. The knee-jerk and superficial reflexes were abolished. There was no cutaneous anesthesia. She had some disturbance of the bladder. Her bowels were usually constipated, but at times under nervous excitement she had an obstinate diarrhœa. The arms were not much affected, though they were weak. She was at times delirious, and had delusions. Vision was not affected. She gradually grew weaker, and six weeks after admission, died. Post-mortem examination: the brain appeared normal, as also did the dura mater of the spinal canal. On opening it an extensive softening was apparent in the lower dorsal region. Aside from the local disturbances there were no gross evidences of disease. Microscopic examination of sections of the cord, showed the most active and recent process appeared to be in the lower dorsal region posteriorly. Here the cord was softened by a process necrotic in nature, which was confined externally by the thickened meninges, and internally by a pretty sharply-defined wall of healthy cord tissue. Lower down at the tenth dorsal this process had extended further anteriorly, until it had nearly cut the cord in half. The softened area in some sections was filled with detritus of nervous tissue, and enlarged blood-vessels were seen near the edge. On the outside was an exudation of lymph. Beside this there was a degenerative sclerosis of the lateral and posterior columns throughout the spinal cord. The process in the lateral column was confined chiefly to the pyramidal tracts, but in the cervical region extended forward, and involved the cerebellar and ascending lateral tracts. The posterior columns showed a slight focus of beginning softening in the lower cervical region, and in the lateral columns the degenerative process seemed rather subacute. It was not a hard sclerosis. The spinal nerve roots were not affected, except the posterior roots in the lumbar region. The morbid process, on the whole, was apparently a subacute systemic degeneration with a terminal focal softening. Associated with the last stage was a local reaction inflammation, with some lymph exudation. The vessels of the cord showed no marked degree of degeneration, and the morbid process could not be ascribed to the blocking up and obliteration. It seemed to be rather a primary and rapid systemic degeneration which was cut short by the focal softening, thus causing paraplegia and death. Pathologically then, the principal characteristic of this case was its rapid course, its primary character, its systemic disturbance, and the terminal softening. The brain was carefully examined, and showed no morbid change.

Dr. B. Sachs said that at the present time it was difficult to agree or disagree with Dr. Dana. The clinical symptoms in his own and Dr. Putnam's cases had varied from the symptoms ordinarily met with in cases of combined sclerosis; but those who had seen many cases of tabes and of ataxic paraplegia and of other forms of combined scleroses would hesitate to create new types on the basis of a slight variation in symptoms. Moreover, they now knew from the investigations of many observers that the degenerations which occurred in the spinal cord were not strictly symmetrical. These often overlapped the lines which divided the spinal tracts from one another. Cases

had been recorded in which the degeneration of the white fibres had also involved the gray matter of the cord. He could not, therefore, see the advantages of creating a special type because the degeneration in these cases happened to be somewhat differently distributed. He must object also to Dr. Dana's suggestion for the suppression of the term, compression myelitis. No doubt that many years ago the term was loosely applied, and in a fair number of cases of compression of the cord the destruction of that organ was not the result of an inflammatory process. It was only within the last few months that Schmaus, in a series of beautiful researches, had demonstrated the extension of the inflammatory process from the bone to the spinal cord itself. In many cases of Pott's disease the symptoms might unhesitatingly be attributed to a true myelitic process.

DR. C. R. ELLIOTT said, that, as to the possible pathology of the changes which took place in the spinal cord in the conditions under consideration, there had, he thought, been much useless discussion as to the precise kinds of degeneration and inflammation which attack nervous tissue. He thought that they might all agree that these changes were reconcilable with those which took place in other organs. In all processes recognized as inflammatory and running a protracted course, there was increase of connective tissue, and results incidental to this. Nervous tissue had an intercellular substance, the same as any other organ with the same parenchyma and protoplasmic material, under certain modifications. In the acute processes the cells underwent more decidedly rapid changes than was the case of the liver, kidneys or heart. In the course of acute processes degeneration might or might not occur. Every process, whether degenerative or inflammatory, was followed by the increase of connective tissue; but the mere presence of this tissue in the nerve substance was no proof as to the initial lesion, whether inflammatory, degenerative or septic, or some process of softening embolism or thrombosis. As to compression myelitis, there was no absolute proof to show that the lesion was inflammatory and he thought that every thing pointed to the contrary. The examinations of the cords in these cases were usually made at a late stage when the changes found and the increase of connective tissue present had given rise to the idea that the processes had been inflammatory from the beginning. Kohler had, however, demonstrated that similar changes could be brought about by mechanical pressure of the cord. In the majority of cases of compression myelitis following Pott's disease there was no tendency for the inflammatory processes to attack any part of the cord. The inflammation was limited to a narrow site on the dura mater. It was only where the process was a rapid one and the perforation of the dura ensued that leptomeningitis and myelitis were set up.

DR. W. R. BIRDSALL thought that the position taken by Dr. Dana was correct, for he was not attempting to establish the existence of a new type of disease of the cord, but was merely calling attention to a group of symptoms differing in course from those of ordinary cases of combined sclerosis. In the opinion of the speaker, compression myelitis was not an inflammation of the cord in the majority of cases. He took exception to the view that placed changes in the cord on a par with those of other organs, and he did not think that they were justified in saying that the inflammatory

processes in the cord and general nervous system were the same as those in other parenchymatous organs.

DR. SACHS said that the remarks he had made in regard to compression myelitis appeared to have been misinterpreted. He was well aware that the term had often been misapplied, but the point he wished to make was, that, in view of the very latest investigations, there was every reason to believe that a true myelitic process was responsible for the symptoms in a number of the compression cases, particularly in those in which a tuberculous process in the bone had been the starting point of the whole trouble.

DR. HERTER had, in Pott's disease, seen direct extension of the inflammatory process from the dura mater to the cord, though the majority of the cases examined post-mortem, were seen at a time when the changes in the cord were purely of a degenerative character and the inflammatory site was not to be seen.

THE PRESIDENT said that it seemed to him that Dr. Dana had made a very useful contribution to the subject. Of course, the paper was only tentative; drawing attention to what he and others had observed. All this part of the spinal cord was a mysterious area, both clinically and pathologically. The author of the paper was perfectly warranted in throwing any possible light upon the subject, and in offering any suggestion based upon observation for the grouping of the pathological conditions and clinical symptoms in this part of the cord.

DR. DANA thought that pathologists generally at the present time would agree with his views as to inflammation. Occasionally it arose from causes other than microscopic poisons, but there was usually some pyogenic germ as the starting point of the inflammation. If it was not possible to get any history pointing to possible entrance of these, he believed it better to withhold any opinion as to the inflammatory or non-inflammatory nature of the lesion. Dr. Sachs's suggestion that there might be tuberculosis of the cord at this level, in some of these cases, might be true; but in the great majority of the cases tuberculous meningitis would not end in sclerosis, but would probably destroy the cord by softening. He agreed that it was well to be cautious in making new types of disease, still such conditions as Putnam had described were not locomotor ataxias or ataxic paraplegias; the prognosis and treatment were different. Prevention or early recognition were important. The condition seemed to depend upon some toxic influence. In pernicious anemia the cord might take on degenerative changes, therefore great attention to the blood was necessary. Recognition of a type was certainly of importance, clinically.

**HYPNOTISM EXTRAORDINARY.**—The *Medical Press* tells a story of a certain hypnotist who "suggested" to a gentleman visitor that he stood *in loco matris* to a troublesome infant whose cries disturbed the peace of the household, and the visitor, having complacently assumed possession of the infant, was left in charge for awhile. The pseudo mother forthwith took the infant off to the Foundling Hospital, just as he would have done had he been really the parent. As he had no recollection of what had transpired on awakening from the hypnotic sleep, a further *séance* was necessary in order to discover the whereabouts of the infant.

KOCH'S TREATMENT OF TUBERCULOSIS.  
OFFICIAL PRUSSIAN REPORT.

A COPY of the official report of the results of Koch's method for treating tuberculosis is before us. This report is compiled from the records of the clinics, poly-clinics and pathologico-anatomical institutes of the Prussian Universities. In answer to the request of the Minister of Public Instruction, fifty-five such returns were made from nine different Universities, with two from non-clinical departments of the Charité Hospital, and two from the Moabit City Hospital of Berlin; and these have been collated by Dr. Albert Guttstadt, lecturer on medical statistics in the University of Berlin, as editor.

The report makes an octavo volume of about one thousand pages, is issued in the form of a supplement to the *Klinisches Jahrbuch*, and covers a period of about two months of treatment from November 1, 1890 to January 1, 1891. Among the reporters are many of the best known medical and surgical clinicians of Prussia: Leyden, Gerhardt, Senator, Fränkel, Bardeleben, Westphal, Olshausen, Schweigger, Virchow (pathologist), von Bergmann, Fränkel, of Berlin; Schultze, Trendelenburg, Finkler, of Bonn; Biernier, Mikulicz, Ponfick (pathologist), of Breslau; Ebstein, Orth, König, of Göttingen; Quinke, von Esmarch, of Kiel; Paul Guttmann, Sonnenburg, of Moabit, Berlin, etc.

The various records, as tabulated by the editor, show 1,768 patients to have been under more or less continued treatment, the number of injections varying from three to fifty-four per patient, and the largest amount of fluid administered to one case being 3,826 grammes in forty-three injections. Of these, 932 suffered from pulmonary tuberculosis; about 120 from tuberculosis of other internal organs; and about 700 from external tuberculous manifestations. The results in these cases are summed up in two tables at the end of the volume, one table comprising all cases of internal tuberculosis and the other all cases of external tuberculosis. In weighing the value of the results given it is necessary to bear in mind the comparatively short

period of treatment—two months or less—and also that the returns come from different sources, so that the tabulation under the four heads of "cured," "much improved," "improved," and "unimproved," must necessarily indicate a somewhat varying standard and a varying duration of treatment. For a small proportion of cases results were not given in the returns.

The opinions expressed by the various contributors as to the diagnostic and therapeutic value of tuberculin vary very much, as might be expected. Senator, for instance, thinks the treatment more successful than any other; Leyden is fairly satisfied with results; P. Guttmann obtains much improvement in thirty-eight per cent. of all cases and in eighty-one per cent. of incipient cases; Schultze and Biernier are not enthusiastic; Ebstein is not hopeful; and at least half a dozen others are reserved in their expression of opinion. These opinions are summed up under several different headings, and occupy forty-three pages, pp. 849-892. A short chapter is devoted to the results of autopsies, and another short chapter contains aphorisms from some of the most prominent clinicians, embodying their experience as to indications and counter-indications for using the remedy in a given case, signs of favorable action, etc.

TABLE I.—Statement of Action of Tuberculin in Tuberculosis of Internal Organs.

Diseases.	No. of cases.	Cured.	Much improved.	Improved.	Unimproved.	Dead.
<b>I.—PULMONARY TUBERCULOSIS:</b>						
1. Early phthisis pulm.	242	9	72	69	98	0
a. With laryngeal tuberculosis.	30	0	10	6	13	0
b. With other internal tuberculosis.	7	0	1	2	4	0
c. With other diseases.	8	0	1	1	6	0
2. Somewhat advanced phthisis pulm.	444	1	68	68	278	6
a. With laryngeal tuberculosis.	85	1	10	11	37	2
b. With other internal tuberculosis.	15	0	1	4	5	2

XI.—TUBERCULOSIS OF STRUTHS OF TENDONS	1	0	1	0	0	0
XII.—SCROFULOUS ECZEMA	1	0	0	1	0	0
XIII.—SCROFULOUS KERATITIS OF BOTH EYES	2	0	2	0	0	0
XIV.—EAR DISEASES	16	0	0	2	14	0
With pulmonary tuberculosis	17	0	0	1	6	0
Totals	708	15	148	237	298	9

The two tables given by the editor are reproduced above, as they show the net results of all the returns in the most condensed form.

This report will repay careful study; but another similar report issued six months or a year hence would have a far greater value. Individual reports of clinical experience with tuberculin in this country could undoubtedly be furnished to-day, having more real value than almost any in this volume, and that solely on account of the lapse of time and the lessons of previous German experience.

#### EXPERIMENTAL THERAPEUTICS OF DIPHTHERIA.

In his address before the Tenth International Medical Congress, Koch said that experiments in therapeutics should be first carried out on the pure culture, and not at the bedside. This would apply especially to those organisms, the cultures of which can be made to resemble closely the morbid conditions in the body. The bacillus of diphtheria described by Loeffler has been studied and killed by several experimenters, but the methods adopted to test the germicidal properties of different substances have been the methods of the chemical laboratory, where the conditions are very different from those which must be met in the treatment of the disease. Recently Loeffler<sup>1</sup> himself has published the results of experiments on pure cultures of his bacillus, which cultures have been made to resemble, as much as possible, diphtheritic tissue. The nutrient material used consists of four parts of blood serum

and one of sterilized bouillon with one per cent. peptone and grape sugar, and one-half per cent. salt; ten cubic centimetres of this is put into a test tube and kept at 37.5° C. The surface of this nutrient material is sown with bacilli, which at the end of eight hours form small colonies, and at the end of twenty-four hours they cover the whole surface with a uniform deposit.

Two problems are presented: the first to prevent the development of the bacillus on healthy tissue, the second, to kill the cultures already growing in and under the membrane. Considering that gargles under the most favorable circumstances cannot be kept on a diseased surface in the throat longer than thirty seconds, the germicidal substances to be tested are poured into the test tube and allowed to remain ten, twenty and thirty seconds, and then poured off, and the vitality of the culture ascertained. Experiments were made in each case both on the recently introduced bacilli and on the thick colonies, and it was found that different substances act better in the different stages, and seem to show that germicides which are perfectly capable of protecting healthy tissue, are useless after the formation of a membrane.

The results with a large number of the applications, which have been recommended for the treatment of diphtheria, are given. Experiments were also made to test the value of different volatile substances, both volatilized and in solution in different solvents. The value of a solvent must of course depend upon the ease with which it permeates to the deepest parts of the culture, and explains the varying efficiency of the same germicide at different stages of the disease, and in different solvents.

Practical suggestions from these experiments, although not introducing anything new, may be briefly summarized. As a prophylactic gargle, solutions of mercury at least every three or four hours are indicated, such as sublimate 1-10000 to 1-15000, or perhaps better, cyanide of mercury 1-8000 to 1-10000. Also, chloroform water may be useful, or chlorine water, 1-1100, or thymol 1-500 solution in twenty per cent. alcohol. A few volatile substances also are of use, which may be applied by inserting glass tubes filled with impregnated cotton, into the nostrils.

After the formation of a membrane the same gargles should be used every hour or two to protect uninvaded tissue and also gargles of more permeating character every three or four hours, such as corrosive sublimate 1-1000, carbolic acid three per cent. solution in thirty per cent. alcohol, or carbolic acid two per cent. solution in equal parts of alcohol and turpentine. Also, direct application by painting the surface is probably of use, which may be done with carbolic acid, five per cent., bromine, two per cent., or chlorine, one per cent. In the diphtheritic throat of scarlet fever, carbolic acid seems to be especially indicated.

The author hopes and believes that better sterilization of the local disease will be found to be the true

<sup>1</sup> Deutsche Medicinische Wochenschrift, March 5.

key to the treatment of the patient, but also points out the possibility of practical results from the recent work of Behring and Kitasato.<sup>2</sup>

#### THE ANNUAL REPORT OF THE BOARD OF HEALTH OF THE CITY OF NEW YORK.

This Annual Report which has just been submitted to the Mayor, estimates the population of the City of New York as 1,631,232.

The number of deaths reported during the year was 40,103, an excess over the mortality in the year 1889 of 424. Notwithstanding the increased death-rate caused by epidemic influenza in the early part of the year, the death-rate for the whole year was 24.58 per thousand inhabitants, as against 25.36 in 1889. The satisfactory decrease in the death-rate during the past decade is believed to be due in a large measure to the diminution of infant mortality brought about by the work of the Board of Health and various charitable organizations.

The number of tenement-houses now in the city is 37,316, and the number of people living in them is estimated at 1,259,788. During the year, 29 tenement houses were closed, as unfit for habitation.

Thirty-nine thousand, two hundred and fifty births were reported, an increase of 9,000 over the year 1885. A considerable decrease in the number of cases of contagious and infectious diseases is noted.

#### MEDICAL NOTES.

**INFLUENZA.**—The daily papers report a severe outbreak of influenza in the West, especially at Chicago and Minneapolis, and later at New York. Reports during the last few months have been received from widely separated districts of its recurrence, generally less severe than last year. New Orleans, Hungary, the Island of Sumatra, and many other places to a less extent, seem to have suffered.

**A TREATMENT OF EPITAXIS.**—Mr. Jonathan Hutchinson has made a note in the *Archives of Surgery* of a treatment of epitaxis which he avers has never failed of success in his hands, and he has had many very rebellious cases. It consists in plunging the patient's feet and hands into water as hot as can be borne.

**THE PHILADELPHIA POLYCLINIC** and College for Graduates in Medicine have established a trust for a fund for an endowment to insure a permanent revenue for the support of the polyclinic library, pathological laboratory, photographic department, prize and other objects. The fund is to be known as the Polyclinic Medical Society Perpetual Fund. The membership of this society is composed of the faculty, assistants, pupils and alumni. On the occasion of the formal opening of their new building on April 2d, a brass tablet will be unveiled, upon which will be engraved the names

of all founders, donors and benefactors of this fund. Founders are those who are eligible to membership in the society and contribute ten dollars. Donors, and benefactors, not necessarily members, are those persons who contribute fifty and five hundred dollars respectively.

**A CONSULATE FOR SURGEON PARKE.**—Surgeon Parke, of the Stanley expedition, has been appointed vice-consul to Oil Rivers protectorate, West Africa.

**PROFESSOR KOCH** is expected back in Berlin at Easter, and will probably travel home via Italy.

**PROFESSOR PFUHL**, director of the chemical and hygienic laboratory of the Friedrich-Wilhelm Institute, has been granted a year's leave from his duties, so that he may be able to assist his father-in-law, Professor Koch, in his further researches on tuberculosis.

**THE DOSE OF TUBERCULIN.**—At the Moabit Hospital in Berlin treatment with Koch's fluid was commonly commenced with a dose of one milligramme, but latterly for a few weeks one-tenth of a milligramme only has been used in many cases, and increased by one-tenth of a milligramme a day for ten days, then by two-tenths every other day until the amount has reached two or three milligrammes, when the increase is made half a milligramme.

**ABSORPTION OF MERCURY BY TAPE-WORMS.**—Oelkers reports in the *Centralblatt für Bacteriologie* that in the case of a patient who was undergoing injections for syphilis, and who also had a tape-worm, he found in the *vas deferens* and *ejaculans* and in the *vagina* of each segment of the worm, small particles of metallic mercury.

#### NEW ENGLAND.

**MEDICAL EXAMINERS.**—Governor Russell has appointed Dr. G. W. Kelly, of Barnstable, Mass., medical examiner of the second Barnstable district, and has reappointed Dr. J. A. Mead, of Watertown.

#### NEW YORK.

**STATE CARE OF THE INSANE.**—The Governor has signed the bill recently passed by the Legislature, appropriating \$451,850 for the purpose of carrying out the provisions of the law establishing State care of the insane poor; an expenditure rendered necessary by the erection and equipment of the additional buildings at the various State hospitals, required for the accommodation of patients transferred from county institutions.

**POLICE MATRONS.**—The Governor has also signed the bill making it mandatory upon the authorities of all cities of over 25,000 inhabitants to provide for the appointment of police matrons for the separate confinement of female prisoners. In New York and other cities the authorities have hitherto refused to act voluntarily under the permissive statute regarding the matter, and this much needed reform in decency and morality is therefore now made compulsory.

<sup>2</sup> See page 1 of the Journal of January 15th.

## Miscellany.

## FIRST ANNUAL REPORT OF THE NEW YORK PASTEUR INSTITUTE.

DR. PAUL GIBIER, Director of the New York Pasteur Institute, has published the results of the preventive inoculations against hydrophobia performed at this Institute during the first year of its existence (February 18, 1890, to February 18, 1891). Eight hundred and twenty-eight persons having been bitten by dogs or cats, came to be treated. These patients may be divided into two categories:

(1) For 643 of these persons it was demonstrated that the animals which attacked them were not mad. Consequently the patients were sent back after having had their wounds attended, when it was necessary.

(2) In 185 cases the anti-hydrophobic treatment was applied, hydrophobia of the animals which inflicted bites having been proved clinically, or by inoculation in the laboratory, or in many cases by the death of some other persons or animals bitten by the same dogs. No death caused by hydrophobia has been reported among the persons inoculated. Indigents have been treated free of charge.

## INFLUENZA IN THE GERMAN ARMY.

THE medical department of the Prussian war-office has furnished statistics of the epidemic of influenza from the medical records of the German army.<sup>1</sup> The name "Grippe" is supposed to be derived from the Polish word "Chrypka," which means catarrh. The epidemic appeared in the army suddenly at the end of November, 1889, and in March was considered as entirely passed. The first cases occurred in the barracks situated in the Baltic provinces, from which place it spread rapidly, the larger garrisons being generally attacked first. There was, roughly speaking, a belt stretching across the country from northeast to southwest, in which belt the epidemic seemed to travel, and outside of which the cases were less frequent and severe. A number of garrisons at a distance from this path, that is in the southeast and northwest, escaped altogether. The time occupied in spreading through the whole army was five weeks, whereas the epidemic of the year 1833 took more than three months. The total number of cases reported was 55,263, of which three-tenths of one per cent. were seriously ill, and one-tenth of one per cent. died. The Bavarian troops suffered the most. The larger number of cases occurred among the younger men, and the smallest number among the artisans. Many other interesting data are recorded.

## OFFICIAL REGULATIONS AS TO TUBERCULIN IN ITALY.

THE question of the use of Koch's fluid by the general practitioner has been studied in Italy with the following result:<sup>2</sup>

At a recent meeting of the Italian Superior Council of Health, the President, Professor Baccelli, presented a report on the Koch treatment, which was referred to a special committee. This committee has now submitted the conclusions at which it has arrived to the

Council. The following is a summary of the committee's report which was unanimously adopted:

The instruction issued by the sanitary authorities on December 14th, provisionally restricting the use of Koch's fluid to university and hospital clinics, is approved of. Circumstances are now changed. The numerous experiments made in Italy and in other countries, and particularly those of Professor Baccelli himself, have better defined the true value of the remedy, and shown the indications for its use, and the possible dangers attending it. The committee, therefore, has no hesitation in proposing that the remedy be entrusted to the hands of individual members of the medical profession, just as they are allowed to use other remedies not less useful and at the same time not less dangerous. Compared with other remedies in the pharmacopœias, however, Koch's fluid presents this difference, that while the purity and quality of these can always be kept under strict control, in the case of the latter there is no other guarantee than the fact of its coming from the institute in which it was originally discovered. The committee, therefore, considers it indispensable that the fluid should be introduced into Italy directly by the central authority, by which also it should be distributed under such conditions and with such safeguards as may be thought advisable. Lastly, the committee recommends that in distributing the fluid, the central authority should at the same time issue the necessary instructions for its use, and should request the medical practitioners to whom it is supplied, to report all the cases in which they employ it, and the results obtained.

## TUBERCULINE.

THE following charade was written by a patient recently under treatment by Koch's method at Banff, Scotland, and sent to the *Lancet* by Dr. William Ferguson:

My first lies at the root of things,  
With homely earth is soiled,  
Yet at the festive board of kings  
Is always welcome — boiled.  
My second o'er the level green  
Impels the polished ball;  
Where "cannons" rattle it is seen,  
Yet loves the peaceful "stall."  
My third around the green earth lies,  
No angel ever saw it;  
'Twas never viewed by mortal eyes,  
Yet men must somewhere draw it.  
When wasting sickness crowns the ill  
By hapless men endured,  
My whole fresh strength and hope instils,  
And whispers "Be thou cured!"

## CARDIAC REMEDIES.

IN a paper by Drs. Rummo and Ferraini, analyzed by Professor Née in *La Médecine Moderne*, December 11, 1890,<sup>1</sup> the authors have endeavored, through experimental studies, to determine which of the cardiac remedies have a special action on the vessels, which on the muscular apparatus, and which on the nervous system of the heart. If, for example, in a case of aortic stenosis one should prescribe a remedy which increases pressure by contraction of the peripheral blood-vessels, the result would still further conflict with the action of the heart; for to a circumscribed contraction which in-

<sup>1</sup> Die Grippe-Epidemie im Deutschen Heere, 1889-90. E. S. Mittler & Sohn, Berlin.

<sup>2</sup> British Medical Journal, March 7th.

<sup>1</sup> Therapeutic Gazette, February.

terferes with the free exit of blood from the left ventricle is added a general stenosis resulting from the contraction of the blood-vessels produced by the remedy.

The authors have shown by their studies that certain remedies, especially caffeine and sparteine, particularly influence the nervous system of the heart. Other remedies, such as helleborin and very particularly strophanthin, produce a stimulating action on the myocardium, while they are without influence on the nervous system of the heart; nerium oleander, digitalin, erythrophleine act principally on the myocardium, while they are without influence on the nervous system, while cocaine and convallamarin act principally on the myocardium; therefore the authors conclude that in cardiac cases, where there is loss of power in the heart, that caffeine and sparteine should be prescribed. When there is feebleness of the heart, occurring in patients suffering from insufficiency and from aortic stenosis, or whenever the resistance is situated in the systemic circulation, recourse should be had to strophanthin, while in mitral stenosis, or where there is obstruction in the pulmonary circulation, recourse should be had to digitalis, adonidin and convallamarin.

With these views Dr. See is in perfect accord, though he regards as an important omission the fact that iodide of potassium is not included in this group, since he believes that there can be no possible therapeutics of heart-affections which do not consider the diuretic action of this remedy and of lactose, and of the influence of the iodide of potassium on the organs of circulation.

#### DRAFT OF A BILL TO REGULATE THE PRACTICE OF MEDICINE IN THE STATE OF RHODE ISLAND AND TO PROVIDE FOR A STATE BOARD OF MEDICINE.

SECTION 1. It shall be unlawful for any person to practice medicine in any of its various branches unless he be a registered physician.

SEC. 2. Any person who desires to practice medicine in any of its departments, perform surgical operations, prescribe for the sick or wounded, cure or pretend to cure by any commonly recognized or special means, for fee or reward, shall appear before any person legally qualified to take depositions and make an affidavit, setting forth the following facts:

That he has practised medicine within the State of Rhode Island continuously for one year previous to the passage of this act. His full name, the date and place of his birth, Date of graduation, and the locality and name of the medical college from which he graduated, if he be a graduate, that the diploma, if he has any, is a bona-fide certificate, and conferred upon him by the institution named therein; if not a graduate he shall state if he has attended lectures at any medical school in this country or elsewhere, when, where, and how long; also, if he has received any other instructions by any one which tend to qualify him as a practitioner of medicine, the date and place, when and where he began practising medicine in Rhode Island, and the names of the places where he may have previously practiced medicine or surgery. Any person who shall in the affidavit required by this section make any false statement, shall be deemed guilty of the crime of perjury and shall be punished according to law.

SEC. 3. He who, under said affidavit, as prescribed in the foregoing section, he has thereupon present said affidavit to the Secretary of the State Board of Medicine, together with his diploma, if he be a graduate, or the person or by messenger. The Secretary of the State Board of Medicine shall keep a book or books for the purpose of recording such affidavits; he shall endorse on such affidavit, over his signature, the date when the same was presented to his record, and the book and page on which it is recorded. The Secretary of the State Board of Medicine shall record all such affidavits, and cause a list of affidavits, arranged in alphabetical order, to be kept complete list of all the names so presented, in one book or book, as before mentioned, and to be called "Book for the use of the Secretary of Medical Practitioners." He shall thereupon cause a certificate to the person making such application and affidavit to be received, of one dollar, and this book or books shall, under seal and at all times be open to public inspection. The Secretary of the State Board of Medicine shall preserve all such affidavits.

SEC. 4. The Secretary of the State Board of Medicine shall issue licenses on blanks prepared as follows:

I do hereby certify that \_\_\_\_\_ has complied with the requirements of chapter \_\_\_\_\_ of the laws of the State of Rhode Island relating to the practice of medicine and surgery, and is hereby authorized to practice medicine and surgery within this State in accordance with the provisions of the aforesaid chapter.

(Seal)

Secretary of State Board of Medicine.

Providence, R. I.

SEC. 5. All persons not provided for in the foregoing sections of this act and who desire to practice medicine within the State shall appear before a board known as the State Board of Medicine, said board to be constituted as follows:

The State Board of Medicine shall consist of seven persons, to be appointed by the Governor on the passage of this act, from among the physicians in good standing, who have practised their profession for more than five years within the State. One member of the Board shall be appointed for the term of one year, one for the term of two years, one for the term of three years, one for the term of four years, one for the term of five years, one for the term of six years, one for the term of seven years.

On the expiration of a year from the passage of this act, and thereafter annually, the Governor shall appoint a registered physician as a member of said Board for the term of seven years. In case a vacancy occurs from death, removal from the State, or resignation, the Governor shall appoint a registered physician for the unexpired term of such member. Four members of said board shall constitute a quorum; said board shall organize by the election of a president and a secretary, both of whom shall sign all certificates and other official documents. Said board shall meet quarterly, and, on the call of their secretary, and may make by-laws and regulations not repugnant to law, for the proper fulfilment of their duties. The presiding officer of said board may administer oaths in relation to all matters connected with or in the administration of the duties of said board. The Secretary of said board shall also be registrar of physicians. The said board shall examine into the qualifications of all applicants for registration, and shall direct the registration by the registrar of all persons properly qualified or entitled thereto. The registrar of physicians shall keep a book in which shall be entered, under the supervision of the State Board of Medicine, the name and place of residence of every person who shall apply for registration. The registrar shall note the fact against the name of any registered physician who may have died or removed from the State, disposed of or relinquished his practice, and shall make all necessary alterations in the locations of persons registered under this act.

SEC. 6. The certificate of the secretary of the State Board of Medicine and registrar of physicians, as to any matter of record of said board, or of the non-existence of any matter of record of said board as to which said secretary may be called upon to testify in his official capacity, shall be admissible evidence in any court in this State of the existence or non-existence of such matter. Said secretary shall be paid the sum of fifty cents for every certificate, which sum shall be taxed in the costs of any proceedings pending in any court in which the same shall be offered as evidence.

SEC. 7. Every person applying for examination and registration shall pay to the State Board of Medicine twenty-five dollars, which in no case shall be refunded, and on passing the examination required shall be furnished free of expense with a certificate of registration. Said board may, at any time in their discretion, discontinue, for good and sufficient cause, any registration previously granted, and shall notify such practitioners thereof in writing. They shall also strike from said list the names of persons who die or move away from the State.

SEC. 8. Every person not a registered physician, who shall, for gain, advise or treat in any manner any person suffering, or supposed to be suffering, from any mental or physical derangement, or who shall, for gain, advise or attend any woman in labor, or who shall, for gain, in any manner imply a willingness to so advise, treat or attend any person, or who shall take, use or exhibit the title of registered physician, and any person who shall violate any of the provisions of this act shall upon the first conviction be fined fifty dollars, and upon the second and every subsequent conviction shall be fined one hundred dollars, and all fines recovered shall inure, one-half thereof to the use of the State, and the other half thereof to the use of the complainant. Provided, however, that any person who shall give satisfactory evidence of her qualifications as a midwife may receive a certificate to that effect from the State Board of Medicine, and after receiving such certificate may attend women in natural labor.

SEC. 9. Nothing in this act shall be so construed as to prohibit or deprive persons from practicing dentistry or pharmacy, nor shall this act apply to commissioned surgeons of the United States Army, Navy, or Marine Hospital Service, or physicians and surgeons called in from other States in actual consultation, or interfere with the sale of patent or proprietary medicines or mineral waters in the regular course of trade.

SEC. 10. All acts and parts of acts inconsistent herewith are hereby repealed, and this act shall take effect sixty days from its passage.

## PRESCRIPTIONS.

BISMUTH FOR ECZEMA OF INFANTS. — The following formulae are given in *Nouveaux Remèdes*:

R Bismuth. subnit.	3 v.
Zinc oxid.	5 lss.
Acid. carbolic.	m. x.
Vaseline.	3 j. M.

To make an ointment.

In case there is much irritation paint on the following with a soft brush:

R Bismuth. subnit.	gr. xl.
Glycerine.	5 lss.
Acid. carbolic.	grs. vj.
Aque rose.	5 iv. M.

To be well shaken.

RESORCIN IN ACNE. — Isaak recommends the following:<sup>1</sup>

R Resorein.	3 j to lss.
Zinc oxid. pulv.	5 jss.
Amyli pulv.	5 iv. M.
Liquid vaseline.	3 v.

Rub on the part affected morning and night, or it may be used at night only, and removed in the morning with sweet oil.

## Correspondence.

## THE KOCH TREATMENT IN MUNICH.

The following extracts from a private letter received from Dr. A. P. Chadbourn, written from Munich under date of March 3d, are of interest:

"Von Ziemssen has, or rather has had, many cases (about one hundred and fifty in all, I think) under Koch's treatment. I have been able to follow them quite closely, as Von Ziemssen allows me to go with him on his daily visits, and thus far I have been the only 'outsider.'"

"His lupus cases have almost all of them done remarkably well, and at this time many seem cured, but they are still coming to the out-patient department, and it may prove a *Besserung* and not a *Heilung*."

"Perhaps a quarter of the cases of *meningitis* (said to be surely tubercular) have 'recovered.' In one instance when the injections were begun it seemed as if the patient could only last a few hours longer, but she is now sitting up, out of bed."

"Less satisfactory are the *pulmonary* cases. Most have gained flesh and strength, but often for a short time only; and in a hospital here the conditions are far better than in the peasants' homes, the contrast being much greater than in America. I cannot see that the Koch treatment has influenced in any way the progress of most of the well-developed cases of phthisis. Some few have steadily gained in weight, with a diminution in or absence of sputum and bacilli, and the rales in the chest have almost or quite disappeared, the subjective symptoms being also much improved. There have been one or two cases of rapid general tuberculosis, but of course the fluid may have had nothing to do with this."

"In the early stages the results have generally been excellent, but I think one would hardly care to say how much is due to the injections and how much to improved surroundings. Later, I hope the gain will prove permanent and due to the new treatment."

"One patient with a large cavity at the apex has been operated on (Sonnensberg's method). The fistula is still open, and we shall see the autopsy before long, I think."

"Very few new cases are now being taken for treatment. Joint tuberculosis I have not seen as much of. Some seem to have done fairly well, but I have not seen enough to be able to say anything about these cases."

## METEOROLOGICAL RECORD.

For the week ending March 14, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Date.	Barometer. Daily mean.	Thermometer. Maximum. Minimum.	Relative humidity. 8.00 A. M. Daily mean.	Direction of wind. 8.00 A. M. 8.00 P. M.	Velocity of wind. 8.00 A. M. 8.00 P. M.	Wet'th. 8.00 A. M. 8.00 P. M.	Rainfall in inches.

York 7, Chicago 6, Washington 3, Brooklyn and Boston 1 each. From erysipelas Chicago 6, Brooklyn 4, New York 3, Philadelphia 2, Boston and Nashville 1 each. From puerperal diseases New York 12, Philadelphia, Brooklyn and Fall River 1 each.

In the twenty-eight greater towns of England and Wales with an estimated population of 10,010,426, for the week ending March 7th, the death-rate was 23.7. Deaths reported 4,547; acute diseases of the respiratory organs (London) 677, whooping-cough 161, measles 160, diphtheria 35, scarlet fever 36, diarrhoea 32, fever 25.

The death-rates ranged from 17.6 in Hull to 33.9 in Halifax, Birmingham 24.4, Bradford 22.5, Leeds 25.5, Liverpool 21.3, London 25.4, Manchester 27.5, Newcastle-on-Tyne 31.6, Sheffield 24.6, Sunderland 28.2.

In Edinburgh 21.8, Glasgow 28.4, Dublin 28.2.

#### OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MARCH 14, 1891, TO MARCH 26, 1891.

By direction of the Acting Secretary of War, Captain WILLIAM C. SHANNON, assistant surgeon, now on duty at Fort Apache, Arizona, will repair to this city and report in person to the Adjutant-General of the Army for further orders. S. O. 55, Par. 5, A. G. O., Washington, March 11, 1891.

Leave of absence for one month, with permission to apply for an extension of one month is granted Captain HENRY P. BIRMINGHAM, assistant surgeon, to take effect upon arrival at Fort C. Barracks, of First Lieutenant ROBERT K. BALL, assistant surgeon, U. S. Army, S. O. 39, Par. 2, Department of the Columbia, March 13, 1891.

#### OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MARCH 21, 1891.

C. J. CLEBORNE, medical director, detached from Naval Hospital, Norfolk, Va., ordered to Naval Hospital, Chelsea, Mass.

T. N. PENROSE, medical inspector, ordered in charge of Naval Hospital, Norfolk.

JOHN M. STEELE, passed assistant surgeon, detached from Coast Survey Steamer "Bache," and granted three months' leave of absence.

JAMES H. GAINES, surgeon, placed on the retired list, March 15, 1891.

M. L. RUTH, surgeon, granted a month's leave, from April 2d next, with permission to leave the United States.

#### OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE, FOR THE TWO WEEKS ENDING MARCH 14, 1891.

LONG, W. H., surgeon. Granted leave of absence for seven days. March 15, 1891.

ALLEN, H. W., surgeon. To proceed to Baltimore, Md., for special duty. March 14, 1891.

GOFFNEY, JOHN, surgeon. Detailed as chairman of board for physical examination of officer of Revenue Marine Service. March 14, 1891.

BANKS, C. E., passed assistant surgeon. To proceed to Boston, Mass., on special duty. March 7, 1891.

PETERS, T. B., assistant surgeon. Leave of absence extended thirty days. March 13, 1891.

HODGINS, F. R., assistant surgeon. Detailed as recorder of board for physical examination of officer of Revenue Marine Service. March 4, 1891.

#### CARNEY HOSPITAL. OPENING OF THE NEW BUILDING.

The new Carney Hospital Building, Old Harbor Street, Boston, was opened on Wednesday and Thursday, March 20 and 21, 1891, from 8 o'clock A. M. to 6 P. M. The Sisters Charity and members of the medical profession and all friends were invited to the institution to visit it at that time.

#### SOCIETY NOTICE

MEMBER OF THE SOCIETY OF THE SUFFOLK DISTRICT MEDICAL SOCIETY. The following is a notice of this section of the Boy's Club. At the day of the year, April 1st, at 8 o'clock.

CONSTITUTION. Dr. C. K. Newell, "The Treatment of Epilepsy, and a New Division for Rapid Duration"; Dr. J. H. Redford, "A Certain Painful Affection of the

Foot"; Dr. C. L. Scudder, "The Clinical Course and Treatment of Chronic Ankle-joint Disease in Childhood." (GEORGE H. MONKS, M.D., Secretary.)

#### OBITUARY. JOHN D. LOVERING, M.D., M.M.S.S.

Dr. John D. Lovering, who died in Newton Highlands, March 18th, was born in Raymond, N. H., in 1827, and graduated at Dartmouth College in the class of 1853. He engaged in teaching a few years in the South and West, then studied medicine, graduating from the Albany Medical School in 1860. He began the practice of medicine in Illinois, but in 1861 settled in Essex, Mass., where he practised for twenty years. A few years were also spent in Manchester, N. H., after which he settled in Newton Highlands in 1883, where he has since lived.

#### DEATHS.

S. PRESTON JONES, M.D., well known as an expert in insanity, died in Merchantsville, N. J., March 13th, aged fifty-nine.

WILLIAM B. SFRAGUE, M.D., President of the Genesee County Medical Society, died in Pavilion, N. Y., March 16th, aged fifty-five.

CHRISTOPHER GOODERAKE, M.D., a distinguished army surgeon during the war, died at Clinton, Ill., March 15th, aged seventy-five years. He was promoted to the post of division surgeon by General Logan.

DR. WILHELM STRICKER, the well-known medical writer, died at Frankfurt-on-the-Main, March 4th, aged seventy-six.

RICHARD MIDDLEMORE, F.R.C.S., of Birmingham, author of several works on the eye, died March 1st, aged eighty-six.

#### BOOKS AND PAMPHLETS RECEIVED.

Transactions of the American Ophthalmological Society. Vol. V. 1888-1890.

The Year-Book of Treatment for 1891. Philadelphia: Lea Brothers & Co. 1891.

Eighth Annual Report of the West End Nursery and Infants' Hospital. Boston. 1891.

## Original Articles.

IN RECURRING APPENDICITIS IS EXCISION OF THE APPENDIX DURING A REMISSION A JUSTIFIABLE OPERATION? AND IF SO, IN WHAT CLASS OF CASES, AND HOW, SHOULD IT BE DONE?<sup>1</sup>

BY CHARLES B. PORTER, M.D.,

*Professor of Clinical Surgery at the Harvard Medical School, Surgeon at the Massachusetts General Hospital.*

For the past years probably no subject has received more attention from the medical and surgical mind than that of inflammation of the appendix vermiformis. The ablest and best physicians have written almost exhaustively on its various and varying aspects. I do not wish in this paper to consider the subject of appendicitis except in its relapsing form. Mr. Treves, February 14, 1888, read before the Medico-Chirurgical Society of London on "Relapsing Typhilitis treated by Operation." This is the first case in the literature on this subject that I have found; though I believe Dr. Thomas G. Morton had previously advocated it. Since that time a number of papers by Robert F. Wier, Dr. W. T. Bull, Dr. N. Senn, Dr. Fred S. Dennis and others have been given to the profession. Some are in favor and some against operative interference in the quiescent stage between attacks. This array of writers on this subject shows that surgeons are considering earnestly the propriety of operation in the period of quiescence. It seemed to me that a collection, an analysis, of these cases in which the operation had been done might help to a decision in what class of cases the surgeon should interfere. It is conceded in the first place that because a patient has had one or more attacks it does not necessarily follow that he will have another. It has been shown by Fitz and others that the percentage of cases in which appendicitis recurs is from seven to thirteen, and analysis of the reported cases in which this operation has been done shows a tendency to increasing severity in each succeeding attack. The length of the period of quiescence varies from intervals so short as to result in chronic invalidism, to months, and in one or two instances to years. The remission stage was marked by almost recovery in some in a short time, and in others extending from weeks into months, resulting in a condition of invalidism. Before reading an abstract of the cases I have been able to find I should like to refer for a moment to some of my own.

About a year ago I reported a case of excision of the appendix for relapsing appendicitis during a remission. The case at that time was too recent to judge of the advantage to the patient or to determine whether it would result in permanent relief. It is now a pleasure to record that there has not been the slightest recurrence of any of the previous symptoms which invalidated him a large part of the time for a year previous to the operation, and which made him afraid to spend a night away from home on account of their frequent occurrence and severity. He is now robust and hearty, attends to his business as well as ever, and so confident of permanent relief that during the last summer he has taken a sea voyage of a number of weeks.

Within a few weeks of my first operation another

case presented itself to me with the following history: Frank B., aged twenty-six, entered the Massachusetts General Hospital, December 7, 1888; four days previous to entrance he was taken with severe pain in the umbilical region, violent nausea, retaining nothing on his stomach except brandy and cracked ice. There was tenderness in the umbilical and epigastric regions, and also in the right iliac fossa, general but not marked tympanites. The vomitus was green and bilious in character at times; at others brownish like coffee grounds; temperature had not risen above 99.8°. Morphine was given subcutaneously and nutritive enemata. Hot fomentations to the abdomen. On the second day after admission a small lump could be felt in the right iliac region, and, by the rectum on the right, a hard mass crowding the anterior wall just above the prostate. A small area felt soft, and in its centre a spot so soft as to suggest pus. On the next day the mass in the iliac region was larger and it was decided to operate. An incision two inches long was made over the outer portion of Poupart's ligament and an inch above it. This was carried down to the tumor, which was aspirated, but no pus found. An assistant then with the finger in the rectum pressed the mass upwards and outwards, and with my finger protecting the iliac artery behind I again introduced the aspirator and withdrew about two ounces of pus. This cavity was opened, and drainage-tube inserted. The case progressed favorably, and was discharged from the hospital about five weeks after operation, the wound closed. In little less than a year from his discharge he entered the hospital again, in the middle of another attack. When asked how many attacks he had had during the year, his answer was, "So many that I have not kept count." His condition was as follows: Pains severe and localized in the right iliac fossa. Tenderness there, but only slight resistance on palpation.

Above the old cicatrix, however, there was a slightly enlarged mass, size of a small plum, tender on pressure. His condition was not such as to demand any active treatment, and in ten days he was practically convalescent. In view of his numerous attacks and his invalidism therefrom, the operation for the removal of the appendix was explained to him, and he was asked to consider it. The next day he requested that it should be done if there was any hope of his recovery.

On December 20, 1889, the operation was done, as follows: An incision parallel with the linea alba, and half way between it and the right anterior superior spine of the ilium, was made, three inches in length and extending to within one and a half inches of Poupart's ligament; all hemorrhage was controlled by hæmostatic forceps. On opening the peritoneum and turning up the omentum, the latter was found attached to the appendix, which was firmly bound down by adhesions and was with difficulty brought up to the incision. A stitch was passed through its tip to lift it and control it while the omentum adhesions were ligated and divided. The proximal end of the appendix for about an inch was firmly adherent to the cæcum, and its walls so thin that in separating the adhesions it ruptured. A ligature was tied between the opening and the cæcum, and the appendix cut off. The lumen of the stump was cauterized with the Paquin cautery. The omentum was stitched to the cæcum in such a manner as to cover the stump. The edges of the peritoneum were united by continuous silk suture, the muscles and

<sup>1</sup> Read before the Boston Society for Medical Improvement, November, 24, 1890.

fascia by interrupted sutures, the skin by interrupted buried sutures. Dry antiseptic dressing applied with swathe. An enema of black coffee was given immediately after the operation, and again in four hours. He made a rapid recovery with no complications. The temperature on the day following rose to 100.8°, and on the next night fell to normal and remained there.

Examination of the appendix by Dr. Whitney: "The outer part of the appendix, 3.25 cms. long, attached to a bit of omentum by strong adhesion. Generally thickened. The outer surface rough, the inner surface smooth. Thickening was shown by the microscope to be in the sub-mucous, muscular and peritoneal coats. The mucous coat normal, chronic periappendicitis.

This case is especially interesting from the fact, that a year prior to the radical operation for removal of the appendix, he had been operated upon for abscess due to periappendicitis from which he recovered in the ordinary manner.

The cases of this operation which I have been able to find are as follows; arranged chronologically according to the date of their publication, because the dates of operation were not always given:

#### CASES BY MR. LAWSON TAIT.<sup>2</sup>

Male, aged twenty-seven. Had had three attacks; in each one the characteristic egg-shaped tumor was present, increasing during the acute stage and diminishing in the quiescent. Operation by an incision over the cæcum about three inches long and about one inch from the anterior superior iliac spine; opened a suppurating cavity outside the cæcum, separated from an indurated mass, the appendix about three times its normal size. Mr. Tait slit open the appendix, and drained it with a No. 6 celluloid catheter. Placed a drainage-tube in the deepest part of the abscess and closed the wound around the catheter and tube. Recovery. Mr. Tait had operated in two other similar cases by removing the appendix, both recovered. He says, "I shall continue to follow the new plan of opening the appendix and draining it independently, until I find some reason to revert to my former practice of removing it."

#### CASE OF DR. N. SENN.<sup>3</sup>

Male, aged twenty-two. Six attacks attended by excruciating pain in the ilio-cæcal region. Vomiting and constipation continuing from one week to twelve days. At Dr. Senn's first examination pain was referred to the ilio-cæcal region, and directly over the location of the appendix a circumscribed area of tenderness could be mapped out. No appreciable swelling, but on deep pressure while the patient's chest was elevated and thighs flexed, a firm cord like body could be felt behind the cæcum over a point corresponding to the location of the appendix. Operation: Chloroform, an incision four inches in length was made directly over the centre of the cæcum and parallel to the ascending colon. The lower angle an inch above Poupart's ligament. The appendix was found behind the cæcum, non-adherent, its mesentery thickened and exceedingly vascular. Its peritoneum appeared healthy. The appendix was uniformly enlarged, and imparted a sensation of unusual hardness. It was ligated with silk, cut off and the pedicle buried

by stitching the peritoneum over it by a continuous suture. Recovery interrupted. Patient is now in perfect health.

#### CASE OF DR. HOEGH.<sup>4</sup>

Male, aged thirty-seven. Five attacks in fifteen months. In earlier attacks general abdominal pains and diarrhoea. In the latter ones pain has been localized in the ilio-cæcal region, severe in character, accompanied by chilliness, no vomiting, but more or less retching, constipation. Abdomen often distended and always tender on pressure over a limited space at a point where the pain always seemed to start. Since last attack unable to resume business. Suffered constantly from pain in the ilio-cæcal region, loss of appetite and increasing debility. Operation: Chloroform, incision through the right linea semi-lunaris, appendix came at once into view lying free in the peritoneal cavity two inches long, remarkably firm to the touch and its serous surface quite vascular. It was ligated and removed. Stump covered by stitching peritoneum from each side with continuous suture. Recovery. The appendix contained a very offensive purulent fluid, consistency of cream, of brownish color. No concretion or foreign body. Two ulcers involved the whole thickness of the mucous membrane. Serous coat near the cæcum was considerably thickened.

#### CASES OF DR. MCBURNEY.<sup>5</sup>

CASE I. Young lady, who in the course of a little over a year, had had no less than twelve attacks of so-called perityphlitis. The attacks were severe, giving rise to great pain with rise of temperature. The operation was done during the period of complete health after careful consultation to prevent recurrence. The appendix was found rigidly swollen, the mucous membrane mildly inflamed, the other tissues of its walls greatly thickened, not the slightest evidence of peritoneal inflammation or adhesion existed. The appendix was readily removed, and the patient made a rapid recovery. Since that time the patient has enjoyed unbroken health.

CASE II. A young lady had had on four different occasions attacks of abdominal pain accompanied by vomiting, exquisite tenderness in the right iliac fossa, and considerable elevations of temperature. Subsequent to the last attack, and during a period of complete health the appendix was removed. The condition of the disease was somewhat in advance of the case last given. The appendix was quite firmly bound down by old adhesions to the under surface of the intestinal mesentery and cæcum. The mesentery of the appendix had been nearly obliterated. The organ was dark colored, swollen and soft and enclosed some fine fecal grains. Two partial strictures existed which produced retention. This patient made a rapid recovery, and four months afterwards was in perfect health.

Dr. McBurney further says, "These two cases show that comparatively slight conditions of inflammatory disease in the appendix may give rise to threatening illness. There can be little doubt that both of these cases were preparing for abscess or general peritonitis."

#### CASE OF DR. WYETH.<sup>6</sup>

Male, aged nineteen. Had had fourteen attacks

<sup>6</sup> *New York Medical Journal*, May, 1890, p. 101.

with an interval of about two months between seizures. Vomiting was a constant symptom in all the attacks, and in about half of them a tumor could be made out, while in the remainder a marked sense of resistance on palpation over the right iliac region was present. Highest temperature reached in any attack was 104° F. At that time pain and vomiting were most distressing, and rectal examination disclosed a tumor occupying the right upper side of the pelvis. Operation: An incision six inches long, the centre opposite the anterior superior spine along the right rectus. After a prolonged search the appendix was found low down in the pelvis below and adherent to the iliac artery and pelvic fascia. Adhesions carefully broken up. The appendix separated from its attachment ligated with silk, removed. Wound closed with silk sutures except at lower angle where it was packed with iodoform gauze so as to shut off the stump from the peritoneal cavity. Reactionary temperature 100° F. Soon fell to normal and remained so. Recovery.

#### CASE OF DR. CLARKE AND MR. GREIG SMITH.<sup>7</sup>

Female, aged twenty-two. Previous excellent health. First attack very severe, colicky pain about the abdomen, not localized. Nausea, slight diarrhoea, headache. She was pale, with sunken eyes and anxious expression; knees drawn up. The least movement gave pain; respiration shallow; abdomen distended, excessively tender, especially in umbilical region; nowhere any dulness nor ascites; stools loose and dark in color; pulse 108, small and weak; temperature 101.5°; convalescence very slow, covering months, and never complete. A second attack about five months after the first, similar to first, but pains were localized in the right iliac fossa. Convalescence protracted for weeks, when Mr. Greig Smith agreed with Dr. Clarke that operation was advisable.

Incision two inches in length, its lower extremity being at the level of the anterior iliac spine and about an inch further inward. The operation was complicated and difficult. Appendix so thickened that it seemed that it would have stood erect without support; appendix removed. Adhesions prevented the invagination of the stump, so the peritoneum was gathered together over the mucous membrane by a continuous silk suture. The appendix contained dark, grumous fluid, with three bodies, which turned out to be orange pips covered with faces and mucus. The mucous membrane much thickened, highly vascular, and numerous hemorrhagic spots, nowhere ulcerated; muscular coat considerably hypertrophied.

Patient immediately improved; temperature normal; recovery. Five months later, in excellent health. No return of pain.

#### CASE REPORTED BY DR. NORMAN BRIDGE,<sup>8</sup>

in which the operation was done by his surgical colleague, Dr. Parkes.

A lady who had had from childhood slight pain in the right groin and thigh, aggravated by exercise, had had some months previously, what appeared a dysenteric attack with pain in the abdomen and especially the right side, with fever. She recovered and resumed active life, to be again within a few weeks seized with abdominal pains, vomiting and constipation. The ab-

domen was tender on the right side from Poupart's ligament to the ribs; no tumefaction discoverable. Daily rise of temperature to 100° or 101°. Thighs kept flexed; tenderness in abdomen persisted for weeks and became more marked over the caecal region. Tentative efforts at sitting up were followed by rise of temperature and return of pain. Laparotomy for exploration of the appendix was decided upon and executed by Dr. Parkes. The appendix was found enlarged, hard and tense, projecting forward in an erect position and deeply congested. It was extirpated and found to contain three small enteroliths, and a quantity of thick tenacious mucus. Its walls were thickened. Recovery excellent, and disappearance of all symptoms.

#### CASE OF DR. MURRAY.<sup>9</sup>

Male, aged twenty-one. Life and habits regular, slight of build, and, at time of operation, very anæmic. The first attack of colicky pains in the abdomen, accompanied by vomiting, general abdominal tenderness, some tympanites, abdominal walls fairly tense. Slight pain on pressure over the right iliac fossa. Tongue coated, bowels constipated. Pulse 96, temperature 100°. Afterwards reached 103°. One month later another attack, and for five months a recurrence every three or four weeks. Comparatively free for five months and then a severe attack. Pain intense and localized in the right iliac fossa. A point of exquisite tenderness over the region of the appendix. Operation: an incision four inches long with its centre opposite the superior iliac spine, on the outer side of the right rectus. Omentum slightly adherent to cæcum; adhesions separated; cæcum lifted into the wound and the appendix exposed. It ran upward and inward behind the cæcum; was enlarged, thickened and doubled on itself. Its mesentery was tied in section; the appendix ligated with strong catgut at its base and cut off. The cavity of the stump scraped, touched lightly with the cauterizer and sprinkled with iodoform. Rubber drainage down to the stump packed round by iodoform gauze. Recovery. Since well. Specimen showed chronic catarrhal appendicitis.

#### CASE OF DR. MONKS.<sup>10</sup>

A boy thirteen months old. Hernia of the appendix into the scrotum. Inflammation and swelling occupying the whole of the anterior part of the right side of the scrotum, and extending a short distance on to the abdomen and inguinal region. Aspiration and free incision. Two weeks later the swelling, heat and redness having gradually disappeared, a long incision in the direction of the cord was made and afterwards extended up to the ring which was freely laid open. The cæcum was drawn out and the appendix removed. The edges of the stump were inverted, sewed together and the whole returned to the abdomen. Examination of the specimen by Dr. Fitz showed chronic adhesive appendicitis. The result of an appendicitis obliterated the peritoneal pouch in which the appendix lay. Recovery.

#### CASE OF DR. HADRA.<sup>11</sup>

A sturdy German baker, aged fifty-two, had frequent attacks during a period of six months marked by colic and constipation, and usually relieved promptly by

<sup>2</sup> Medical News, May 21, 1890.

opiates and enemata. He became accustomed to treat himself. Seen by Dr. Hadra in a more severe attack six weeks before operation. At that time, in addition to the ordinary symptoms, the caecal region was resistant to the touch, but no distinct tumor could be felt. There was a spot the size of a silver half-dollar about two inches inside the anterior superior spine of the ilium, which was extremely tender and which was insisted on as the site of the pain in every attack. Operation by crescentic incision of about six inches, convexity to the right. On opening the peritoneum the appendix presented at once; was two inches long, thicker than a common pencil, had a complete mesentery and was nowhere adherent. Its peritoneum seemed slightly clouded. It was tied close to the cæcum and cut off. The stump rubbed with iodoform cotton and closed by three Lembert sutures. Pathological report by Dr. Dock given at length, but summed up in the following sentence: "Look on the specimen as an example of chronic catarrhal appendicitis of mild grade." Recovery. Pain and tenderness disappeared, and four months after the operation there had been no return.

Now, from a careful study of these cases, I find that the decision in favor of operation was made in all on account of the frequency of recurrence and the severity of the attack, and where the persistent localization of the symptoms in the region of the right iliac fossa lead to the conviction in the mind of the operator that the appendix was the offending organ. All who are familiar with the clinical history of appendicitis are fully aware of the difficulties which surround the diagnosis in some cases. Still there are many so typical in their symptoms as to leave little doubt as to the nature of the disease. In such, it seems to me, the surgeon should be ready to present to the sufferer something more than medical treatment, which means temporary relief from pain or the other alternative, to wait until an attack is so severe and threatening to life as to demand immediate operation, and this at a time when the patient is least able to bear the shock and when a careful preparation for an aseptic operation can be inadequately made. As to the danger to life of this operation it is certainly remarkable that in all the cases which I have been able to find an account of, including my own, fifteen in number, all have made excellent recoveries. The number is too small to draw any general conclusion as to mortality, and there are probably some cases which I have not been able to find which have ended mortally, and also some unfortunate, but unpublished, due to the tendency to suppress unfavorable cases. Nevertheless, it is an encouragement to the surgeon to hold up to a suffering patient a good prospect of relief from operation. It has been urged as an objection to surgical interference that there is a lack of evidence that removal of the appendix brings immunity from the symptoms requiring it. No answer can be given to this except by experience. In my own two cases there has not been the slightest recurrence of the old symptom since convalescence was established; and in the second case in which relapses had been so frequent as to make them almost continuous, the patient expressed great surprise that, even with the wound in his side, he was absolutely free from all pain or discomfort after operation.

Many of the reported cases are published simply as recoveries, but in four the length of time since opera-

tion is stated as four, five, six and seven months each. In my own cases one has had complete relief for more than a year, and the other for only a few days short of that, so that in six cases relief is known to have been given for a period of from four months to a year.

The danger of ventral hernia at the site of wound has been adduced as an objection to the operation. All surgeons are well aware of this danger in all laparotomies, and endeavor to prevent it by the most careful approximation of the peritoneal surfaces as well as the rest of the wound. We do not hesitate to make an exploratory incision to ascertain if we can give relief to many conditions no more threatening to life than appendicitis, and in cases with very little prospect of relief compared with what we might expect in many cases of relapsing appendicitis. The final answer to this operation must be deferred until time sufficient has elapsed to gather data, and until a larger number of cases can determine the per cent. of such accidents. I hold also that this danger should be plainly stated to the patient before operation, so that his decision can be intelligently made. Certainly a wound made in the period of remission which could be closed in a large percentage of cases immediately and throughout its whole extent with careful approximation of the peritoneal surfaces would be less apt to result in a ventral hernia than one made when the parts are acutely inflamed and the presence of pus makes an open wound with drainage imperative. I have found in the analysis of the above cases that though many of them presented no very great difficulty, there was some in which the appendix was found after prolonged search, and requiring of the surgeon a refinement of touch, and accurate acquaintance of the anatomy of the region and thorough knowledge of the variable position of the appendix.

Mr. Greig Smith says, in his case: "After minute examination by sight and touch, no sign of vermiform appendix could be made out; the cæcum and adherent bowels were drawn up towards the surface, a minute digital examination revealed somewhere in the depths of the coherent mass a line of increased resistance in which certain hard movable bodies were detected, and this, it was inferred, must be the appendix. Pulling the cæcum towards the upper abdomen, put the appendix, for such it was, upon the stretch, and it was easily followed into the depths of the pelvis. Its apex was attached on the posterior surface of the broad ligament." I will not complete his description, but this much shows what may be encountered. He afterwards mentions two cases which were abandoned on account of the difficulties, and later referring to his case from which I have made the above abstract says: "I do not hesitate to say that any one who had not some considerable experience in the surgery of the abdomen and full confidence in his sense of touch might have been unable to finish it." Other cases have presented complications that were equally embarrassing.

By some who do not favor the operation, it has been suggested that each recurrence throws around the appendix an increasing wall of inflammatory product, hemming it in, and decreasing with each attack, the danger of intra-peritoneal rupture. This may be to a certain extent true, but the same mass adds greatly to the difficulty of finding the appendix should the case subsequently require operation either

from the severity of the attack, or because other reasons make an operation in a remission desirable. It would therefore seem wise in such cases as threaten the necessity of operation to operate early.

My conclusions then would be:

(1) The operation with its attendant difficulties and possible danger should be presented first, to those in whom a condition of invalidism is produced by the frequency or severity of the attacks; second, to those who are prevented from performing their ordinary duties in life; third, to those whose surroundings are likely to be such that they cannot in time of urgent necessity, command the services of an experienced surgeon (this would apply to those whose home was where good surgical skill was not available and those who travel by land or sea, and are likely to be seized with an attack at a distance from home).

(2) That the surgeon should be sufficiently familiar with abdominal surgery to be able to meet the difficulties which he may encounter.

(3) That in such cases as threatened the necessity of operation, it is better to do it in a remission, when those preparations of the patient, instruments and dressings can be made which are requisite to an aseptic operation.

#### OPERATION.

An incision should be made along the outer border of the rectus, curved or straight, about three inches long, in such a manner that the centre of the incision shall be over the usual site of the appendix. This can be made larger later if complications arise which demand it. This can be made with a free hand until the peritoneum is reached. This can be recognized by the *præ* peritoneal fat. All bleeding points should be tied or controlled by hæmostatic forceps, and the wound made dry before the peritoneum is opened. This should be done the full extent of the wound. The appendix should be sought, and if not seen the finger introduced into the wound. The touch will often determine the location of the appendix, which is usually thickened or feels rounded and tense from the retained secretions.

#### METHOD OF REMOVAL.

The appendix should, when found, be separated from its attachments—from its mesentery by tying it in sections and division with the scissors, and from surrounding adhesions by gentle pressure with the finger or sponge. Any bleeding is best controlled by pressure with sponges or gauze. Ligation may occasionally be needed. The appendix should be ligated with silk near to the cæcum and removed, great care being used that none of its contents escape into the wound.

#### TREATMENT OF THE PEDICLE.

I have found in my cases that it was impossible to invert the edges and suture the serous surfaces, and have treated the lumen of the appendix like the cervix uteri in an hysterectomy by the actual cautery, and then stitched a flap of omentum over its top, the stitches being placed in the shape of a horseshoe with the open part towards the centre of circulation in order not to impede it. In this way the pedicle is quickly shut away from the general abdominal cavity by the adhesion of the omental flap. In some cases it has been possible to invert the edges of the pedicle and suture them. That is a good method where

practicable. I believe that the cautery is safer than dusting the cut surface and lumen with iodoform, boracic acid or aristol, and of the three I should prefer the last.

#### THE TREATMENT OF THE WOUND.

The cavity of the wound should be thoroughly cleansed and in suitable cases should be closed throughout. The peritoneal surfaces should be approximated independently by a continuous or interrupted silk suture, then the rest of the wound by silk sutures. In one case I closed by three sets of sutures: the first closed the peritoneum; the second, the muscular and aponeurotic structures; and the last, the skin, by a buried suture. The wound healed throughout by immediate union, and up to the present time there has been no tendency to hernial protrusion. In cases where pus or the contents of the appendix have escaped into the wound after thorough cleansing, it should be packed with iodoform gauze, and in some cases a drainage-tube is required. The immediate closure of the whole wound averts as far as possible the danger of ventral hernia.

#### AFTER-TREATMENT.

Immediately after operation a subcutaneous injection of an eighth of a grain of morphine to be repeated *p. r. n.*, a rectal injection of four ounces of black coffee to be repeated in two hours, if there is any shock. Absolute diet for two days. Nutritious euemata during this time, then liquid diet for about a week, if the case is progressing favorably. Dressings should not be disturbed for ten days, unless indicated by the temperature. Stitches removed in fourteen days. The patient then allowed to sit up in bed, and to be about in four weeks, unless there is some special contra-indication.

#### A REPORT OF SIX MONTHS' WORK IN THE OUT-PATIENT DEPARTMENT FOR DISEASES OF WOMEN AT THE BOSTON CITY HOSPITAL.<sup>1</sup>

BY DR. CHARLES M. GREEN AND DR. GEORGE HAVEN.

ALTHOUGH the daily routine of an out-patient clinic rarely offers much of conspicuous interest, it has seemed to us that an hour might profitably be spent in analyzing before you our work of the last six months at the Boston City Hospital, and in listening to the criticisms and suggestions which we hope our paper will elicit.

The clinic, which, in common with the other out-patient departments, except the surgical, is amply and conveniently accommodated in the new out-patient building, occupied early in 1890, is held on three days of the week: the period covered by our report, July 1 to December 31, 1890, therefore includes seventy-eight clinic days. On these days we have received 1,279 visits, of which number 350 were new patients: the average daily work of the clinic consists, therefore, of seeing 16 or 17 patients, of whom 4 or 5 are new. The ratio of new patients to old, as we see them, is as one to three. This large proportion of new to old patients is due to the facts that many women after examination and diagnosis are referred directly to the Admitting Physician and are not seen by us again, and secondly that numerous cases come from out of town for a diagnosis and an opinion only, and of course

<sup>1</sup> Read before the Obstetrical Society of Boston, January 10, 1891.

do not become regular attendants; further it will be seen later that a certain proportion of our cases has required but one or two visits from the nature of the condition found.

The facilities for examining and treating patients, and incidentally it may be said for teaching students, are vastly superior to the accommodations of the old building which had been our home until 1890: ample waiting room, a large consulting room, and two examining rooms with instruments in duplicate, blackboards, and every desired facility except an electrical plant, which will, we are confident, be provided in the future, not only enable the medical staff to do better work and better teaching; but the opportunities for a becoming privacy and the moral effect of the attendance of a nurse at all examinations have led thither a larger number of patients to seek advice. In the period covered by this report, 329 more visits were made to the clinic than in the corresponding period of the preceding year when we were lodged in the old building. Or if the attendance of the year 1889, which was the last whole year in the old lodge, be compared with that of the year 1890, which was almost wholly spent in the new building, it will be seen that the latter exceeds the former by 725.

In seeking to report the results of our work we find ourselves seriously handicapped by the want of carefully taken histories and subsequent records. Any one who has worked much in out-patient clinics is well aware of the great demands made upon his time, and knows that if he does justice to his patients there is little time in a busy morning to devote to accurate, careful and systematic case-taking. In our work we have tried to remember that the chief object of the clinic is to benefit those who seek advice there; secondarily, we have endeavored to make full use of the opportunities afforded us to teach the students attached to the clinic. The pursuit of these two objects has left us little time for systematic record-keeping; but we have sought always to make an accurate diagnosis at the patient's first visit, and thereafter, except in cases of unusual importance, which are kept in a specially prepared record-book, subsequent notes are jotted down in the register as opportunities occur.

For these, and other reasons, we do not undertake to analyze our old cases, but present for your consideration the 350 new cases of the last six months. Of these women 240 were married, 11 were widows, 95 were single, and in four instances the civil status was not recorded. We classify the cases as follows:

DISEASES OF THE VULVA.	
Eczema . . . . .	2
Chenion (traumatic) . . . . .	1
Vestibulitis . . . . .	1
Achylitis . . . . .	1
Achyl-vaginal abscess . . . . .	1

Total lesions or conditions observed . . . . .	422
Deduct for patients counted more than once . . . . .	72
Total number of patients . . . . .	350

It will be observed that in this classification we have endeavored to base our diagnosis on anatomical or pathological conditions, and have avoided as far as possible making a symptom stand as the name of a condition or disease. It will be further noticed that when the same patient is affected with more than one lesion or pathological condition, each lesion or condition is classed under its appropriate head, and the proper deduction made for patients counted more than once.

We now propose to comment on some of these cases, either singly or in groups; but before doing so, we would call attention to one matter of general importance in respect to treatment. It will be remembered that a very large proportion of all hospital patients are hardworking people. Many who attend the woman's clinic are fagged-out mothers of families, or over-worked household servants; some are degraded. Nearly all are suffering with some other affections than those

which strictly fall to the gynecologist's care: tired nerves, dyspepsia, constipation, headaches, and numerous other minor ills are usually found associated with the pelvic troubles, whether or not they are dependent on, or are aggravated by, them. In dealing with this, to the gynecologist, often uninteresting class of cases, we have always sought to relieve concomitant symptoms whether or not they are thought to proceed from the pelvic condition. Even when there has been reason to think that all the symptoms are explained by the local lesion, we have learned to believe in the wisdom of administering appropriate general treatment in conjunction with local measures of relief. In some cases we are able to accomplish little or nothing in the way of local treatment: successful gynecological work presupposes intelligent co-operation on the part of the patient, and a more or less complete control. It is hardly worth while to undertake to treat an acute or subacute pelvic inflammation, for example, in a patient who is unable to take any recumbent rest, who is too poor to provide herself with the facilities for taking suitable vaginal douches, and who is too unintelligent to carry out other measures that may be advised for her relief. Scientific and highly successful work in the treatment of diseases of women must be looked for chiefly among the well-to-do classes and in hospitals. Out-patient departments can palliate disease, relieve symptoms and in a certain proportion of cases cure: for the rest their administrators must be content to observe, to teach, and to learn.

Of the diseases of the vulva none were seen of especial interest except the case of traumatic edema, which was said to have followed a kick. The labia were much swollen, and there were a few abrasions: rapid improvement followed the use of evaporating lotions and black wash.

The case in which the vagina was absent is of interest, from the rarity of the deformity. The patient was a young girl just past puberty, who was brought to the clinic because she had never menstruated: in general appearance she was well developed; but no history could be obtained of a menstrual molimen. Without anaesthesia it was impossible to determine whether or not the uterus and ovaries were also absent; but the patient was admitted to the service of Dr. Cheever, and it was proposed to examine under ether and proceed in accordance with the ether diagnosis. Unfortunately, however, the patient took fright and did not reappear.

The case of vaginal atresia associated with sloughing of the cervix, and following labor, craniotomy and septicæmia will be made the subject of a special paper. A sufficient time has not elapsed for marked contraction of the vaginal lumen to have taken place; but the case will afford a considerable obstetrical interest, if pregnancy shall supervene a year or two hence.

While we have discriminated in our classification between simple and gonorrhœal vaginitis, we do not claim to be able to make a positive and scientific distinction between the two forms, except with the microscope. And yet it is generally possible, from history and macroscopic appearances of vulva, vagina and patient to differentiate with sufficient exactness between a gonorrhœal vaginitis and one due to non-specific irritation. In the benign, non-specific inflammation, removal of the cause, with cleanliness and astringents have always proved efficient. In true

gonorrhœal vaginitis a germicide should precede other treatment. Happy is she whose gonococci are overtaken and destroyed before they have eluded pursuit in the folds of the Fallopian tubes.

Senile vaginitis appears to be an affection *sui generis*. It occurs in women long past the menopause and after atrophic changes have taken place in uterus and vagina. It is almost always associated, whether as cause or effect, with sleeplessness, irritability and other evidences of general nervous instability. We have found that the disturbance is readily overcome by a systematic course of bromides and tonics, and a few astringent applications.

In the one case of undeveloped uterus, the depth of the cavity is one and three-fourths inches; without ether the condition of the ovaries has not as yet been determined. The patient is well-developed in other respects and is desirous of bearing children; but nothing has yet been attempted in the way of treatment. Possibly an intra-uterine electric stem might be of service in such a case.

The seven cases of conical cervix with pin-hole os have been treated by gradual dilatation with Hanks's dilators, and marked improvement has followed in those cases which complained of dysmenorrhœa. Whether or not the canal will remain permanently enlarged after suspension of treatment remains to be seen; but there is reason to believe that the relief is more than temporary. Our method has been to dilate at first once every week, except in the menstrual week, and follow with an intra-cervical application of strong carbolic acid. After a few weeks, dilatation is performed less frequently, and finally only once in the month, to wit, just before the expected catamenia. In cases wherein this method is not effective, we recommend forcible and extreme dilatation under ether, with Goodell's instrument, with the subsequent use of a perforated glass or hard-rubber plug stitched into the cervix and allowed to remain for ten days, the patient meanwhile being kept in bed.

Among the inflammatory disturbances there was one case of cervical atresia due to some operation which had been undertaken for the relief of dysmenorrhœa. The patient menstruated, but with great pain, and we were unable to pass even the smallest sized probe. No method of relief suggests itself other than incision, dilatation and possible introduction of a glass plug.

The cases of cervicitis were treated with iodine and carbolic acid, in conjunction with the hot douche and glycerine tampon. Some few were advised to have the cervix curetted. Two cases of endocervicitis received practically the same treatment. Seven cases of chronic endometritis, the result in nearly every case of abortion, were advised to enter the hospital.

Fourteen, or four per cent. of the total number of cases, find their proper place in the group of new growths. These were as follows: interstitial fibroma, one; subperitoneal fibroma, three; mucous polypus, three; hypertrophy of anterior lip of cervix, two; epithelioma of cervix, five. Only one of the cases of fibroid gave any trouble, and this was from pressure. Electricity would possibly have diminished its size, but could not be used as we were not provided with the apparatus. The cases of mucous polypus were either sent to the house for operation, or the growth was removed while the patient was on the table. Five cases were of epithelioma of the cervix, or nearly one-

third of the total number of cases in this group. They were for the most part advanced beyond all hope of radical treatment, the uterus being fixed, and infiltration having taken place in the cellular tissue. They all gave histories of hamorrhage for various periods, usually months, and one case for more than a year. The flow was in almost every instance bloody, but we recall one case where there had been no hamorrhage, the discharge being merely an offensive, yellow, mucopurulent one. They all supposed that the flow would stop, and had never before sought advice. They only made the old truth plainer, that hamorrhage from the uterus frightens the average woman but to a very slight degree. They did not come so much on account of the flowing, as on account of general weakness which was growing steadily greater. They were all advised to enter the hospital.

Under the head of displacements we have grouped all cases where the uterus occupied a distinctly pathological position. In all, 127 such cases were noted. Of these 56 were displacements backward, divided as follows: retroversion without adhesions, 32; retroversion with adhesions, 11; retroversion and flexion, nine; and four cases of retroflexion.

In the cases of retroversion where adhesions were not present the uterus was replaced in one of several ways: either by placing the patient in the knee-chest position, and pushing the cervix backward with the aid of a tenaculum; or in the Sims position, using the tenaculum in the same way; or else the uterus was seized by one hand on the abdomen assisted by the fingers of the other hand in the vagina and so brought into proper place. After this pessaries were used to maintain the corrected position. We wish to emphasize our disapproval of any instrument designed for replacing the uterus, as the uterine sound or repositr, believing that its use, even in skilful hands, is not unattended with danger.

Where adhesions were present the patient was placed in the Sims position and packed every five days. If tenderness existed, the hot douche and glycerine tampon preceded the packing. In no case was ether given and adhesions broken up by force. We believe, and not without cause, that the forcible separation of adhesions, even when done by skilful operators, and when the patient is in the most profound state of anaesthesia, is not unattended with danger. In some few cases adhesions running from the posterior uterine wall to the rectum may be felt and possibly separated by force; but, we can never be sure that adhesions do not run in other directions, and the force which separates them is often sufficient to start up pelvic inflammation, the result of which, in many cases, is more serious than the trouble for which the persons first sought relief. One or two of these cases are still under observation. Treatment in the other cases was successful and they merely return from time to time to have their pessaries cleared. The time occupied in replacing uteri by the methods employed varies from a few weeks to several months. Some of the cases were sent to the hospital later for needed operations on the cervix and perineum. The one case not mentioned was of lateral version, the uterus being pulled by adhesions (the result, undoubtedly, of some old inflammatory process) toward the right side. The cases of retroflexion received the same treatment as the retroversions and do not require any special comment. We have not recorded a single case of anteversion, which

we think only emphasizes the extreme rarity of this position of the uterus in a pathological sense. In such of the thirty-four cases of anteversion, whether of cervix, corpus or both, as showed symptoms attributable to this lesion, we have sought to straighten the canal with sound or dilators and support the uterus with tampons,—these measures affording relief in some cases. When, as in some of the cases of anteverted cervix, there was also prolapse, we have found benefit in the use of the Thomas or Emmett pessary; which not only corrects the prolapse, but by raising the uterus from its seat on the posterior vaginal wall allows the uterus to straighten itself and thus remove the anteversion. We have not in any of these cases employed any form of so-called anteversion or anteversion pessaries, believing that in the out-patient class of women, at least, such instruments are liable to do more harm than good.

Among the thirty-six cases of prolapsus uteri there was observed every variety of descent from the simple prolapse in first degree to the single case of complete prolapse with inversion of the vagina. In many cases there was associated with the prolapse a forward or backward displacement; in other cases there was laceration of the cervix with hyperplastic enlargement, with perhaps tears of the perineum and vagina with rectocele or cystocele or both. In the treatment of this numerous class of cases we have been limited to non-operative procedures, and have referred to the admitting physician cases needing house treatment. In the other cases treatment has been directed to lightening the uterus and supporting it when necessary with a suitable pessary. To fulfil the former indication nothing is so efficient, when properly administered, as the hot water, vaginal douche. As the low bending branch, loaded with fruit, rears itself when lightened of its burden, so will oftentimes the uterus, when disengorged of blood, rise to its normal level. Many minor cases are successfully treated simply with the blood-dispelling douche and perhaps the temporary support of tampons; in conjunction with which local treatment, however, tonics and roborants are usually necessary, to improve the muscular tone and the better to enable the uterine ligaments to support the womb. In other cases, especially in such as require plastic operations, but refuse them, pessaries are necessarily used; but owing to the well-known liability to subsequent neglect in this class of patients, pessaries are used as infrequently as possible.

Forty-nine women, or nearly one-seventh of the whole number, had sustained a laceration of the cervix, although the lesion was not in all cases attended by symptoms. Simple fissures, which may be called physiological, are not included in this number, but only tears which extended through the crown of the cervix. No attempt has been made to classify the cases according to unilateral or bilateral lesion, nor again according to the degree of the tear, nor according to the presence or absence of hyperplastic enlargement, cystic degeneration, or erosion. The routine local treatment of these cervicæ has been the opening of cysts when found, cleansing with a two per cent. solution of creolin, painting with Churchill's tincture of iodine, and placing a tampon wetted with a ten per cent. mixture of iodoform in glycerine. This treatment is administered once a week, the tampon is allowed to remain two days, and a depleting hot douche is ordered for the remaining five days. Appropriate general treatment

is prescribed as a matter of course. A few weeks of persistent treatment will usually reduce the cervix in size, remove all cysts and heal erosions. If then the tear is a deep one, if there is marked erosion and hyperplasia, the patient is advised to enter the house for operation, if otherwise prepared. If, on the other hand, these conditions are absent, no operation is advised simply because of the tear. Cases in which there is a well-founded suspicion, based on gross appearances, of a beginning epitheliomatous degeneration, are promptly recommended for admission to the hospital, without waiting for the usual preliminary treatment, which in such cases would be of no particular value.

Twenty-nine cases are classed as diseases of the appendages. Four of these were supposed to be ovarian cysts. They were observed for a time and then sent to the hospital for treatment. Prolapse of the ovary is recorded seven times. In most of these cases the ovary was movable and the symptoms were somewhat relieved by the use of iodine, tampons, the hot douche and rest. Some of them fell into place when the patient was put in the knee-chest position. When a pessary could be used, relief often followed its application. The cases which were associated with backward displacement of the organ were very much benefited by having it replaced. In the cases where adhesions were present little was accomplished by treatment.

Seven cases occur under the heading of tubo-ovarian. The diagnosis was not always clear; but the tube and ovary were supposed to share in the pathological process. These cases were treated with the hot douche, iodine, light packing, and rest; and certainly very satisfactory results were not obtained. The same may be said of the ten cases of salpingitis. Some of these have drifted away from observation and probably seek in other clinics the relief which they failed to obtain with us. Some few were relieved, and others advised to enter the hospital for operation.

We have also classed among this group one case of pelvic peritonitis, believing it belongs here on account of its etiology, the germs which caused it undoubtedly finding their first home in the appendages.

Among the functional diseases, the six cases of amenorrhoea were all traceable to anemia and debility. The patients were given iron or arsenic with general hygienic treatment and several of the cases have already begun to menstruate again, while others are still under treatment.

The five cases classed as "constipation" by no means embrace all who were thus functionally disturbed. There were five women in whom constipation seemed to be the sole disturbance and cause of symptoms: speaking roughly there probably were not many more than five women in the whole number in whom the function of defecation was normally performed. In nearly all patients, therefore, we are obliged to consider this function. We endeavor, in so far as our time and the patient's intelligence will permit, to give advice as to the dietetic and hygienic management of constipation. In the way of drugs we have found that on the whole the fluid extract of cascara sagrada is the most satisfactory: in some cases pills of aloin, strychnia and belladonna serve better.

Among the other classified troubles we find notes of three cases of cystitis, one case of incontinence, and six of cystocele. There also occur five cases, among the unclassified, of rectocele. The cystitis and incontinence require no special mention. The cases of

cystocele were usually associated with rupture of the perineum, and gave more or less trouble in proportion to the extent that the bladder was involved.

The five cases classified as rectocele were possibly incorrect, inasmuch as notes were not made as to whether the rectum was involved in the prolapsing process in each case; and if we note Schroeder's comments on rectocele, we shall be inclined to think that more than half of the cases classified as such were in reality nothing but prolapse of the posterior vaginal wall. As far as treatment is concerned little can be done in an out-patient clinic for this class of cases. Hot douches, tampons soaked in some astringent solution, as glycerite of tannin, gave a certain amount of relief. Most of them, however, were sent to the house, either for operations upon the perineum, or for anterior and posterior colporrhaphy.

The ten cases of perineal rupture, of which two were through the sphincter ani, do not include any of the minor tears, but only those of sufficient extent to necessitate surgical treatment: and such cases were referred to the Admitting Physician. The minor degrees of rupture, not included in our classification, we could, of course, do nothing for, except in the way of remedying by pessary or other treatment the vaginal or uterine displacements of which they were more or less the cause.

Thirty-four women, or nearly one-tenth of the whole number of new patients, were found to be pregnant. In some cases the patient came for the relief of some affection incident to pregnancy; but in most instances the women came to find out whether or not they were pregnant. So large a contingent is of no especial value to a gynecological clinic, except in so far as it affords excellent opportunity for teaching, and for cultivating the ability to diagnosticate pregnancy in the early months. In examining for a suspected pregnancy attention is directed to the vulva, the appearance of which is often suggestive to the practised eye; to the vaginal introitus, with intent to observe the blue discoloration, if present; to the cervix and lower uterine segment, for characteristic changes; to the size and shape of the uterus, as ascertained by bi-manual examination; to the abdomen, in the later months, with a view to inspection, palpation and auscultation; and to the breasts, for their characteristic appearances. No detailed record has been kept of the presence or absence of specific symptoms; but we may say, in a general way, that we have not found the peculiar, violet tint of the anterior vaginal wall below the urethra so frequently as some other observers appear to have done. In regard to the breast changes, we would bear evidence to their great value as diagnostic signs in the early months, when bi-manual palpation of the uterus is sometimes inconclusive and unsatisfactory. Indeed, of so great value are these signs, that a probable diagnosis of pregnancy has often been made in the clinic, in spite of a history and other signs to the contrary, or at all events of a negative character; and we do not recall a case in which the probable diagnosis was not subsequently confirmed. Of course it is unwise to express any opinion to a patient of a positive nature that is not founded on positive knowledge; but it is extremely convenient to the physician to be able to make a diagnosis of sufficient probability to govern his treatment and future course of action: for this reason we teach our students never to neglect an inspection of the breasts in cases where pregnancy is suspected.

## REPORT OF PROGRESS IN GYNECOLOGY.

BY F. H. DAVENPORT, M.D.,  
Instructor in Gynecology, Harvard Medical School.

## EFFECT OF THE CONSTANT CURRENT ON MYOMATA.

GUSTAV KLEIN,<sup>1</sup> as the result of experiments on myomata which had just been removed by laparotomy has formulated the following effects of the constant current:

With a strength of current up to one hundred milliamperes and a duration of from five to sixty minutes a five-fold result was shown.

(1) Chemical, through the development of acids at the positive and of alkalis at the negative pole. This effect seemed the most important.

(2) Electrolytic, a chemical disintegration taking place, which was most apparent through the development of gases.

(3) Thermic, the temperature being raised at both poles, in many cases as much as ten to fourteen degrees Centigrade.

(4) Injury to arteries, veins, and lymph vessels, which can be so great that they become practically useless. The gas which forms at both poles drives out the fluid contents of the vessels which are pierced by the needle electrode, and both walls and contents are so changed that they are no longer pervious to fluids.

(5) Physiological effect on the muscular fibres of the myoma and its vessels, which expresses itself first in contraction, and later in relaxation.

The details of the numerous experiments must be studied in the original.

## EXPERIMENTS ON THE PRODUCTION OF PERITONEAL ADHESIONS AFTER LAPAROTOMY.

Dr. Kelterborn,<sup>2</sup> as a result of experiments in this field, has come to somewhat different conclusions from other investigators. Sanger concluded that after resection of the parietal peritoneum, a single raw surface sufficed for the formation of adhesions, and that there was no regeneration of the endothelium, but adhesions followed of necessity.

The results of v. Dembrowski are briefly as follows: Foreign bodies, ligatures with the corresponding ligatured ends, and eschars certainly produce peritoneal adhesions; iodoform, blood-clots, irritating and antiseptic fluids, and the various lesions of the peritoneum are without influence on the formation of adhesions.

As a result of eighteen experiments on cats, dogs, and rabbits, Kelterborn arrived at the following conclusions: Losses of the epithelium and eschars of the peritoneum do not lead in uncomplicated cases to the production of adhesions. Ligatures in the abdominal cavity rarely cause adhesions, but usually become encapsulated. By far the most common cause of adhesions after laparotomy is infection, there is, therefore, no objection to the free use of the thermo-cautery in separating adhesions.

## TRANSPERITONEAL HYSTEROGRAPHY.

Dr. F. King,<sup>3</sup> after a fairly complete *résumé* of the various operative measures advocated for the cure of obstinate backward displacements uncomplicated by

adhesions, describes what he calls transperitoneal hystero-rhaphy. It is briefly as follows: The uterus is pushed forward against the abdominal wall by a sound. A very small incision, three-quarters to one-and-a-half inches in length is made over the fundus in the linea alba down to the serosa, but not going through it. A needle is then passed entirely through the abdominal walls, and is felt between serosa and fundus. A special needle with a cutting edge on the back is used, and with this about a square inch of the anterior surface of the uterus is denuded. The needle is then passed through the body of the uterus and brought out on the opposite side of the incision. A second suture is passed in the same manner. These are tied and the wound dressed in the usual way. It is a short operation, five to eight minutes, does not open the abdominal cavity, and in six cases operated on by the writer, there was complete success.

## MECHANICAL OBSTRUCTION IN DISEASES OF THE UTERUS.

Dr. George F. Hulbert<sup>4</sup> has a very interesting and instructive article on this subject. His excuse for presenting it is, that the result of his observations and experience is entirely at variance with the consensus of medical opinion and practice. He says that in more than ten thousand women seen in his hospital and private practice, he has not found a single case which satisfied him that mechanical obstruction existed or was the disease.

He explains his views at some length; first, as to the normal or natural order of things as related to structure and function, he proceeds to demonstrate by certain principles of physics that the uterus is capable with one-fourth of an inch aperture at the point of exit, and one inch depth of cavity, of discharging more than thirty-eight thousand ounces during the twenty-four hours, with one thirty-second inch aperture we find a capacity equal to over six hundred ounces in twenty-four hours.

Second, as regards the pathology, the author claims that as a flexion is usually of slow development, there is not a narrowing of the canal at the point of flexion, as in a bent rubber tube, but that a process of atrophy at the concavity of the angle, and of hypertrophy at the convexity takes place so that the V-shaped wedge of tissue at the convexity of the angle is not present, and the canal remains patulous. The other conditions of mechanical obstruction, conical cervix, pin-hole os, congenital or acquired, partial or complete stenosis, are never sufficient to cause any obstruction to the discharge of "fluid blood," which he says is all that the uterine canal can justly be called upon to permit to pass. He excepts, of course, atresia.

Such being his conclusions he explains the symptoms usually ascribed to mechanical obstructions by the theory that they "are produced within the tissues, and are dependent upon disturbed rhythm of physiological forces evolved by abnormal innervation, muscular action and circulation."

In accordance with these views the therapeutic measures which are most successful are reconstructives, narcotics, anodynes, anti-spasmodics, muscular tonics, and last but not least, electricity, and all surgical and mechanical methods which are not assisted by pronounced improvement in the systemic nervous and nutritive forces of the patient will be ineffectual.

## EXPLORATORY PUNCTURE OF THE FEMALE PELVIC ORGANS.

Dr. G. M. Edebohls<sup>6</sup> describes in a paper with the above title a method for the differential diagnosis of slight enlargements or masses situated either entirely in the pelvis or projecting but slightly above the brim of the pelvis, and which are recognizable only by combined abdominal and vaginal touch.

The method is briefly as follows: The mass to be punctured is located and steadied by the middle finger of the left hand in the rectum, and the index finger in the vagina, the rectal finger, if possible, reaching to the upper limits of the mass, the vaginal finger being applied to its lower pole. By combined palpation a point on the anterior abdominal wall directly over the centre of the swelling is located, and the needle of a syringe is carried into the middle of the mass. The piston is then withdrawn by an assistant.

Dr. E. has practised this method in over seventy cases without the least untoward result. He expressly limits it to cases where a satisfactory diagnosis cannot be made without it. The guarantees of safety are: (1) Perfect asepsis; (2) immobility of the syringe and needle; and (3) resistance of the temptation to bore about in the tissues with the needle.

In thirteen out of fourteen cases of pyosalpinx and ovarian abscess he had proved by this method the presence of pus before laparotomy. In three cases of hæmato-salpinx he had been able to make a diagnosis by exploratory puncture, and as a result had avoided three unnecessary laparotomies. Puncture in another case of tubal pregnancy revealed the presence of blood free in the peritoneal cavity. In a case of fibroma this method revealed the presence of co-existent disease of the appendages and decided the question of therapeutics in favor of salpingo-oophorectomy as against electricity. In one case he diagnosed the carcinomatous character of a small tumor of the right side of the pelvis.

In conclusion he advocated caution in the use of the method, claiming that it aspires to the dignity of a somewhat exact and scientific procedure, and that only those who possessed a fair degree of skill and experience in bimanual palpation of the female pelvic organs should attempt it.

## OPERATIONS FOR FIBROIDS.

Dr. A. Martin<sup>6</sup> gives in this interesting paper a fairly complete account of his experience with the different methods of operating for fibroid tumors of the uterus. It will only be possible to refer to some of the more important points discussed by the author, the finer details of which must be sought in the original.

Dr. Martin divides treatment into therapeutic and operative. Under the first head he includes ergot and electricity. As regards ergot, he says, that while he has occasionally seen a cessation of hæmorrhage and some shrinking of the tumor from its use, yet he has never observed a definite cure of the tumor, and has seen bad effects from it. He advises against its long-continued use, if improvement does not quickly follow.

Electricity he has used in ten cases, and had under observation two others in which it had been used, and of these twelve cases he was obliged to operate on

five. There was improvement in the symptoms in some of the other cases, but he considers this method of treatment is not yet beyond the experimental stage, and urges caution in its use.

The operative procedure which he considers are: (1) Enucleation by the vagina, (2) removal of the uterus per vaginam, (3) enucleation of pedunculated subserous tumors after laparotomy, (4) extirpation of the tumors with the whole genital apparatus.

Castration he does not consider, as he has not performed it for the purpose of producing the menopause in cases of fibroids since 1886.

The enucleation per vaginam should be reserved for tumors of moderate size which have been forced well into the cavity of the uterus, and where the cervical canal is either patulous or can be easily made so.

The removal of the whole organ by the vagina can only be thought of in cases where there exist a large number of small fibroids in a uterus of moderate size and easily reached. The author has operated nine times in this manner.

The majority of fibromata which demand operative treatment can only be reached by laparotomy. Pedunculated tumors can naturally be treated by ligaturing the pedicle and removal. Dr. Martin advocates the enucleation of intraparietal growths, thus saving ovaries and uterus capable of performing their functions. This method he has applied in ninety-six cases, and in spite of unfortunate circumstances which increased the mortality, considers it a procedure which should take precedence of the more radical operation in all suitable cases.

The extirpation of the myomatous uterus by laparotomy is applicable to cases of numerous and large tumors, where it is impossible to preserve any useful proportion of the uterus. The author's cases number one hundred and thirty-five of which he lost forty-six, a mortality which he considers anything but satisfactory. As regards the method of operating, the mortality as well as other difficulties, especially in the treatment of the stump led him in 1888 to modify the operation so as to remove the whole organ, including the cervix. The technique of the operation, and the interesting histories of the thirty cases operated on in this manner must be read in the original. There were eight fatal cases, one from embolism, three from anæmia, two from paralysis of the bowels, and only one each from sepsis and secondary hæmorrhage.

## Clinical Department.

FIBRO SARCOMA OF BOTH OVARIES; COELO-TOMY; RECOVERY.<sup>1</sup>

BY W. H. BAKER, M.D.

THE case, from which the specimens which are now before you, were removed, seemed of sufficient interest to bring before this Society, from the fact that it illustrates to what extent this disease may progress without occasioning any marked suffering to the patient; and also from the fact that an error in diagnosis was made, which was only corrected at the time of the operation.

Mrs. M. first consulted me November 22, 1890, and gave the following history: She was forty-seven years

<sup>6</sup> New York Medical Journal, November 29, 1890.

<sup>6</sup> Zeitsch. für Geb. und Gyn., XX Band, I Heft, 1890.

<sup>1</sup> Read before the Obstetrical Society of Boston, January 10, 1891.

of age, had been married twenty-three years and had had six children, the oldest of whom was twenty years of age and the youngest six years. She had had one abortion before the birth of the first child. Her menstruation, which had begun at the age of fourteen, had continued normal, although for the past year it had been quite scanty. There had always been more or less leucorrhoeal discharge complained of, but this symptom had nearly disappeared of late. Her general health had never been robust. No malignant disease in her family. Her labors had all been natural. She had been feeling "badly" for more than a year, and thought she had not felt as well since the birth of her youngest child as before that time. She was unable to be on her feet any length of time without suffering from pain across the lower abdomen of a bearing-down character.

Examination under ether on November 24th, showed the presence of a nodulated mass to the left of the uterus, which extended quite around behind that organ. The first impression conveyed to the touch was that this mass was immovable in its position, but by placing her in an exaggerated Sims's position, it could be dislodged into the upper pelvis without changing the position of the uterus. The diagnosis which seemed most probable at that time was of a distended tube of the left side, filled with inspissated pus. The end, being trumpeted out, was lying behind the uterus, the nodular feel being given by the convolutions of the tube.

The operation of ovariectomy<sup>1</sup> was advised, and subsequently performed (January 5, 1891). The only point of interest at the time of operation was the similarity in size and general appearance of the ovaries, so much so that when the second was brought through the abdominal incision, I turned almost instinctively, to be sure that its fellow had really been removed. The pedicles were thoroughly seared with the thermocautery. Over the surface of the peritoneum covering the uterus and forming the broad ligaments, and to some extent over that membrane reflected on the abdominal parietes, were to be felt small elevations like those found in tubercular deposits. After several times flooding the peritoneal cavity with hot water, the incision was closed. The recovery was uneventful.

The ovaries were referred to Dr. W. F. Whitney for examination, who returned me the following report:

"The specimens received from you yesterday represent both ovaries and Fallopian tubes. The latter are of normal size and perversions, although the fibriated extremity of one is partly bound down to the ovary. The ovaries are enlarged to about the size of a small apple, the surface is coarsely nodular. Section shows a firm, rather fibrous looking surface, quite uniform and slightly white. Microscopic examination shows this to be made up of fibrous tissue with bundle of large spindle-shaped cells, and here and there bands of what appear to be large, flat, endothelial-looking cells. The diagnosis is fibro-sarcoma; and from what you say, and also from the small nodules in the fold between the ovary and tubes I fear that it has already infiltrated the peritoneum."

The population of Boston, according to the figures of the Census Office as finally revised, is 448,177.

<sup>1</sup> As suggested by Dr. Harris, of Philadelphia, as a substitute for ovariectomy.

## HYPERTROPHY OF ANTERIOR LIP OF CERVIX AS A POSSIBLE BAR TO PREGNANCY.<sup>1</sup>

BY EDWARD J. FORSTER, M.D.

M. W., twenty-six years of age, married, born in Germany, entered the City Hospital December 15, 1890, for treatment for sterility, dilatation of cervix if found necessary. Patient had never had a child, but one year ago had miscarried at third month, during which occurrence she continued up and about, performing her household duties.

Examination found the parts normal, excepting a very long hypertrophy of the anterior lip of the cervix, of which the accompanying cut gives a better idea than any description by words. The hypertrophied lip was soft and easily movable, and upon coition was probably forced backward, and thus occluded the os.

A Peaslee sound was easily passed, so that stenosis of the os could not have been a factor in causing the sterility for which the patient entered the hospital, and any dilatation of the os was of course unnecessary.

Under ether the enlarged lip was removed, and the specimen sent to Dr. F. H. Sears, who returned the following report:

"Small, tongue-shaped piece of tissue, covered with apparently normal epidermis. On section, fairly translucent, with few opaque, white lines running longitudinally. Microscope showed hypertrophy of normal tissue, with some dilated vessels and lymph spaces. Diagnosis: hypertrophied cervix."

Whether the hypertrophy was congenital or not, cannot be stated positively. The parts operated upon united by first intention, and the patient was discharged with a possible bar to a future pregnancy removed.

## Reports of Societies.

### THE OBSTETRICAL SOCIETY OF BOSTON.

CHARLES W. TOWNSEND, M.D., SECRETARY.

THIRTIETH ANNUAL Meeting, January 10, 1891.

DRS. GREEN AND HAVEN presented

A REPORT OF SIX MONTHS' WORK IN THE OUT-PATIENT DEPARTMENT FOR THE DISEASES OF WOMEN AT THE BOSTON CITY HOSPITAL.<sup>1</sup>

DR. BAKER was much pleased with the paper, which he hoped would be published in full, and he could testify to the absolute soundness of the methods of treatment employed. The full classification was particularly interesting and well arranged. In his experience

<sup>1</sup> See page 329 of the Journal.

<sup>2</sup> Read before the Obstetrical Society of Boston, January 10, 1891.

lacerations of the cervix were not quite so common as the readers had found. As to the method of overcoming adhesions in the gradual manner described in the paper in detail, Dr. Baker considered it one of the wisest and best methods we possess.

DR. BLAKE spoke of the great value of Alexander's operation, about which the readers had not spoken. As to dilating the cervix in cases of dysmenorrhœa and sterility, he himself uses for several months perforated glass tubes after the dilatation, and it would seem as if the ten days recommended by the readers was too short a time. The paper as a whole, he considered of great value and interest.

DR. HAVEN said that no mention was made of Alexander's operation as only those operations which could be done in an out-patient department were considered.

DR. BLAKE believed it doubtful whether the adhesions which bind a uterus down are absorbed. They are certainly very elastic and yield in this way. Of late he had heard of pushing the hand down behind the uterus in women with thin abdominal walls, the fingers being pushed up in the rectum at the same time.

DR. SINCLAIR said that this was a form of massage of the pelvic organs, a form of treatment which he considered of the greatest value, which was, however, still in its infancy. For the last twenty-five years he has practised it largely, and is convinced that no form of treatment, not even packing, breaks up adhesions better. It requires great skill and delicacy of touch but he feels sure that it is a form of treatment which has come to stay. Of late years he has entirely given up packing the vagina for this purpose.

DR. BLAKE differed from the readers in his views on the use of repositors, which he thinks of great value, and has not had bad results from their use.

DR. F. H. DAVENPORT said that the chief value of a paper like Dr. Green's was in its suggestiveness as to new and effective methods of treatment. The class of patients who are treated in our out-patient departments are naturally often unable to follow the line of treatment which would be the best for them. Being for the most part hard-working women, they are unable to give up the time required for an operation, and find it equally hard to take the rest which is of so much aid in many gynecological affections. The problem, therefore, is to find modes of treatment which will interfere the least with their regular occupations, and which will in the shortest time enable them to do their work with comparative comfort.

In my service at the Boston Dispensary I have found one or two procedures of value. First, in cases of prolapse of the uterus and vaginal walls, where a pessary could not be retained, I have found the following method effective. A large wad of cotton tied around the middle so as to constrict it into the shape of a dumb-bell is freely covered with tannin and glycerine, and placed in the vagina, pushing it firmly against the vault of the vagina. This will usually stay, and every second or third day it is removed and a fresh one placed. After two or three weeks of this treatment I have not infrequently found that the uterus would remain in its normal position. I have explained it on the same theory as the cure of prolapse by the There-Brandt method, of forcibly pushing and pulling the uterus up into the pelvis, that by putting the ligaments on the stretch improves their

tonicity, and so strengthens them. Second, in the treatment of retro-displacements with adhesions, I usually begin with packing in the usual way. After a few packings if the position of the uterus does not continuously improve, I place the patient on the back, and drawing down the uterus with a tenaculum, I attempt to raise the fundus with one or two fingers in the vagina. This will often result in a distinct gain. I then resume the packing, and after a few times repeat the attempt at manual reposition. By this combination of the tampon, and an occasional more forcible elevation of the uterus with my fingers, I am confident I often materially shorten the time of treatment.

DR. EDWARD REYNOLDS said that details of treatment such as had been brought out by the paper, were of the utmost interest. In out-patient work he had found the old-fashioned vaginal pontics of great use. These were simply small cylindrical bags of cheese cloth filled with linseed meal, to be dipped in hot water and changed by the patient every three hours. In cases of beginning prolapse a lacerated perineum with lack of support is generally found. Patients of the working class often will not submit to an operation for its repair, and Dr. Reynolds does not dare to put in a hard rubber pessary on account of the danger of injury to the parts from neglect of the patient to have the pessary cleansed. For this reason, he uses as the lesser of two evils the old-fashioned doughnut pessary, and gives with that much relief. Outerbridge's instrument he has used in cases of sterility in one or two cases and with success. He regretted that the readers were unable to report as to the use of electricity, which he regarded as of great value, but by no means a cure-all.

DR. ROWE said that as soon as the staff decided on the proper form of electrical apparatus it would be supplied them.

DR. STRONG said that he believed that the forcible separation of adhesions in a retroflexed uterus was a thoroughly safe operation if skillfully done. Only one case of this sort gave him any anxiety, that one leaving the hospital suddenly against advice, and having a cellulitis start up. She has since done well.

Repositors he believed to be perfectly safe instruments to use, and in some cases he failed to get the uterus back without their use.

In some patients a support fails after a time to correct the backward displacement, and in these cases Alexander's operation is often of the greatest value. Lately he has not used anterior supports and has relied entirely, as did the readers, on raising the uterus with prolapse supports, and has obtained much better results. Backward displacements which seem to be bound down with adhesions, are often, he believes, uteri which have slipped down through the sacro-iliac ligament, and here it is that massage, by gradually working them up, is of such great use.

He was rather surprised at the small proportion of tubal disease, which he finds considerably greater at the clinic of the Massachusetts General Hospital. He asked Dr. Sinclair whether he had packed with the patient on the side or in the dorsal posture.

DR. SINCLAIR replied that he had always packed in the dorsal position.

DR. GREEN in closing, said he had never dared to forcibly break up adhesions in an out-patient service and let the woman walk home, an opinion with which Dr. Strong agreed. The tampon treatment allows the

patient to continue work without pain, and she feels better all the time. If the patient were at home or in an hospital he would not hesitate to use a certain amount of force. He believes strongly in the truths of Emmet's statement that the overcoming of prolapse rather than of the backward displacement, is the thing that relieves symptoms.

Dr. HAYEN criticised Dr. Reynolds's use of the doughnut pessary, which he believed stretched the vagina more and more, and required constantly enlarging sizes of supports.

Dr. E. H. BRADFORD reported briefly

#### A CASE OF SALPINGITIS,

where the patient suffered great pain and tumors were to be felt. The patient was unable to continue in her profession of dancing. Dr. Bradford operated, removing tube and ovaries, which he showed to the Society. The result of the operation was very favorable.

Dr. E. J. FORSTER reported a case of

#### HYPERTROPHY OF ANTERIOR LIP OF CERVIX AS A POSSIBLE BAR TO PREGNANCY.<sup>2</sup>

Dr. BAKER reported a case of

#### FIBRO-SARCOMA OF BOTH OVARIES; CÆLIOTOMY; RECOVERY.<sup>3</sup>

and showed specimens.

### JOHNS HOPKINS MEDICAL SOCIETY.

MEETING Monday evening, March 2, 1891.

Dr. HENRY THOMAS reported a case of

#### CEREBRAL SYPHILIS.

Patient, a man of good physical appearance, entered the hospital one year ago, complaining of headaches, double vision, ptosis of the left eyelid, anæsthesia on the right side of his face. The left pupil was greatly dilated. The external rectus was the only healthy muscle of the eye. The right eye responded sluggishly to light.

He had been under treatment at the Eye and Ear Infirmary, and his sight had improved. It was found by subsequent inquiry that his external rectus had been paralyzed, but that a course of anti-syphilitic treatment had completely restored its action.

All of his reflexes were exaggerated on both sides. On admission to the hospital he was able to walk, but this power was rapidly lost. The third nerve (motor oculi) was completely paralyzed and the fourth (patiens) was somewhat involved. It was thought that there must be a tumor of the left crus in order to affect the third nerve and cause opposite hemiplegia at the same time. The patient was given anti-syphilitic treatment, though no external evidences of syphilis could be found. On the tenth day after admission he became comatose, with slight twitchings of the right arm and leg, and died.

At the autopsy the vessels at the base of the brain were found to be in a condition of gummatus arterio-sclerosis. Three gummatus nodules were found in the basilar artery; a large gumma on the left crus, involving the third nerve, another pressing on the left fourth. The fifth (cranial) was adherent to the men-

inges; a large gumma encroached upon the sixth; another involved the right olivary body.

The interference with the trifacial had caused the anæsthesia; the paralysis of the external rectus of old standing, which had been cured by mercurials, had come from the gumma on the sixth (abducens). On the left third was a large gumma. The meninges were inflamed the entire length of the cord, but the arteries were not markedly degenerate. In the upper part of the lumbar enlargement was a degeneration in the anterior horns. The cells had atrophied, and there had been an infiltration of blood, possibly caused by a degeneration of the walls of the vessels.

*Summary.*—There was in this case a condition of gummatus arterio-sclerosis; an infiltration of round cells into the arteries, owing to the degeneration of the walls; and many gummata throughout the base of the brain.

Dr. TOULMIN reported an interesting case of

#### LEUKÆMIA.

Patient, a woman, aged thirty-three years, married, a cook, presented herself at the gynecological department of the hospital February 25th, suffering from what she considered a tumor of the uterus.

The history of the case was as follows: Patient's mother and father had both died when patient was very young. She had been fairly well until last fall, when first seen at the dispensary. She had had repeated miscarriages, and in January, when seen again, she was too weak to work, suffered from severe pain in the left side of her abdomen (where the swelling was), coughed badly, had obstinate constipation. No epistaxis; no palpitations; no œdema until recently; and until recently no shortness of breath. On entrance pulse was 120; respiration good; no capillary pulsation; temperature 100.7°. Her skin had a very sallow hue; all the mucous membranes were anæmic; and just below the ribs could be felt a hard movable tumor, on the left side. She denied having had malaria or any specific disease. There was no tenderness or enlargement of the bones, no glandular swellings, no diarrhœa. She was given Fowler's solution, three minims to begin with, gradually increasing to thirteen minims three times a day, with marked improvement in the condition of the blood and great reduction in size of the spleen, as may be seen from the following measurements:

	Sept. 15.	Jan. 29.	Feb. 25.
Circum. abdomen at tumor, middle.	91.5 cm.	94.5 cm.	95 cm.
Circum. at umbilicus . . . . .	91.5	90.5	90
Midaxillary dulness . . . . .	7th rib	8th rib	8th rib
Lowest edge from pubic bone . . . . .	7 cm.	4 cm.	7 cm.
Lowest oblique diameter . . . . .	41	48.5	43
Extent of right edge from median line, 3		10	3

March 2. The dulness was still as low as 7 cm. above pubic bone, and the right edge 2.5 cm. from median line. The oblique diameter of tumor was 35 cm., and circumference of abdomen 74.5 at middle of tumor, and 74 at level of umbilicus.

Blood count was as follows:

First week . . . . .	{ Red, 2,171,000 } 1:3.
	{ White, 714,000 }
Third week . . . . .	{ Red, 2,779,339 }
	{ White, 33,000 }
Fourth week . . . . .	{ Red, 2,647,333 } 1:354.
	{ White, 7,500 }
Fifth week . . . . .	{ Red, 2,779,333 } 1:397.
	{ White, 7,000 }

Hæmoglobin tests were very difficult on account of the multitude of white globules. The Zeiss hæmometer is used in counting the number of cells, and the

<sup>1</sup> See page 346 of the Journal.

<sup>2</sup> See page 346 of the Journal.

count is made several times for accuracy in each case.

Description of the blood (percentages) in this case of leucocythemia is as follows:

	Jan. 29.	Feb. 1.	Feb. 13.	Feb. 21.	Feb. 23.
Red corpuscle, lymphocytes . . .	96	1.5	2.7	6.9	7
Mononuclear transition forms. Normal = 6% . . . . .	3	1.5	2.1	2.5	2.3
Polynuclear neutrophilic. Normal = 60-75% . . . . .	70	83.9	84.7	83.2	78.1
Eosinophile. 2-5% . . . . .	2.3	4.2	1.6	3	4.4
Myelocyte. Not found in normal blood. Characteristic of splenic myelogenous leukemia . . .	23.5	8.6	8.5	4	4.7

In splenic myelogenous leukemia there is an enormous increase of (1) lymphocytes and of (2) myelocytes, (3) a large number of nucleated red globules, (4) large increase of myelocytes or mononuclear cells with neutrophilic granules.

There were also found several degenerate forms of red globules, as shown in the experiment of their taking basic coloring matters. Large numbers of megablasts were seen. Erlich has described these as degenerative forms, but we have seen them in process of division. May these be the early forms of red blood formation?

DR. KELLY reported several interesting

#### HYSTERECTOMIES

in which the stump was suspended in the cavity by means of wires instead of being drawn up to the abdominal opening, to slough off in time, or of being left without support in the peritoneal cavity. His results have been excellent.

### Recent Literature.

*Etudes sur la Rage, et la Méthode Pasteur.* Par le Dr. LUTAUD, Rédacteur-en-chef du *Journal de Médecine* de Paris. Deuxième édition. Précédée d'une lettre de M. le Professeur Peter, et contenant les statistiques complètes depuis l'inauguration de la méthode jusqu'en 1890. 8vo, pp. x, 440. Paris: Journal de Médecine. 1891.

The spirit of the volume with the above title is sufficiently indicated by the first words of the letter written to the author by Professor Peter and published as an introduction, "I agree with you upon all points, the so-called preservative treatment against rabies of Pasteur is both an error and a danger."

The volume is a summary of the criticisms of the method of preventive inoculation against rabies by its most virulent opponents, and contains a hostile review, not only of the work upon rabies and its results, but upon everything that Pasteur has ever done.

So far as rabies is concerned, the assertions made in this volume are not borne out by the statistics published monthly in the "*Annales de l'Institut Pasteur*," and, unless these are false, our author's conclusions are unjustifiable.

The personal attacks upon Pasteur and his motives are such as should find no place in a volume that pretends to scientific accuracy and value. H. C. E.

*Flushing and Morbid Blushing: Their Pathology and Treatment.* By HARRY CAMPBELL, M.D., B.S. (Lond.). 8vo, pp. x, 270; with 21 illustrations. London: H. K. Lewis. 1890.

The present volume is a careful and elaborate study of certain very common symptoms, which, not attaining great importance in the mind of the physician, although often very distressing to the victims, have received scarcely any attention from medical writers. A flush is regarded as a small but complex nervous storm, commonly manifested by three phases, heat, sweating and cold, which may occur in any order, and one or two of the phases may be absent. The flush manifests itself by dilatation and contraction of the cutaneous vessels, and by excitation of the sweat-glands. The vascular change is no indication of the condition of the vessels below the dermic papillae; the sweat-glands are probably excited by trophic as well as by vaso-motor nerves. An elaborate study is made of the frequency with which the three phases occur, their order, the distribution and progress of the flush, and other symptoms which may attend the three phases of the flush, the time of occurrence, the etiology and the pathology. Morbid blushing is observed usually in persons of an unstable, emotional type, and is closely allied to the flush, although excited more invariably by psychical causes. Both symptoms indicate a defect in the nerve centres, often a general and radical defect of organization, and consequently the treatment must be general. This leads the author to give a "philosophy of the general treatment of nervousness," a study of the poisoning of ganglion-cells by abnormal blood plasma, and the disturbance of ganglion-cells by the nervous impulses that strike upon them. In regulating these conditions, the author calls attention to the various educational methods, hygienic measures, and forms of treatment, especially the modifications of the so-called Weir Mitchell treatment. This section, although containing little that is new, contains much that is suggestive. The work itself is most elaborate, and deals with these common but little-studied symptoms in a most exhaustive manner.

*Epilepsy: Its Pathology and Treatment.* By HOBART AMORY HARE, M.D., B.Sc., etc. 12mo, pp. 228. Philadelphia and London: F. A. Davis. 1890.

This volume, the seventh in the Physicians' and Students' Ready Reference Series, is the essay to which the Royal Academy of Medicine in Belgium awarded a prize of four thousand francs, which the author modestly regards as the chief excuse for its publication. The reviewer, however, in view of the fact that monographs in English on epilepsy are few and far between, that most of them, too, are of poor quality, and that there is no work which sums up the recent progress that has been made in our knowledge, can find in the merits of the present work a sufficient reason for its existence, apart from the award. Dr. Hare has based his work upon the study of 970 cases which he has collected, supplementing the data thus obtained by an exhaustive examination of the literature. After a brief glance at the history, he studies carefully the symptoms, the causes, the pathology and the treatment. Firmly believing in the idea that all epilepsies are essentially centric, may more, cortical, he admits the possibility of epilepsies of reflex origin, starting with a peripheral aura, and apparently due to

an impulse rising in the periphery; but he holds that in such cases the peripheral irritation has set up central changes, perhaps of slow development, and not necessarily permanent at first. In time, however, the continued irritation causes repeated discharges, and the epileptic habit becomes fixed. Hence the author occupies a very conservative position as to regarding refractive errors, adherent prepuces or pelvic disturbances as causes of epilepsy. The old vascular theory is shown to be untenable. It is needless to cite the various theories which are quoted as efforts to explain epilepsy. Many of them have been abandoned, others are still on trial. Various lesions have been found after death, among the most constant being sclerosis of the cornu ammonis. The author's own position seems to us eminently safe and sound. "Epilepsy does not signify a disease, but a symptom of a disease." It is essentially symptomatic of "a cortical disease of the cerebrum, brought about in many ways. Either direct irritation of certain cells may so result, or indirectly, by irritation of a reflex character, they are perverted from their normal function. No one, he he ever so wise, will be able to tell the reader the ultimate cause of the nervous discharge which causes the attack, until some one has discovered the manner in which the remote something, which causes nervous protoplasm to give forth impulses, acts." Of the chapters on symptomatology and diagnosis we have room to say but little; but that little is that they afford a most complete summing up of modern views, and hardly a symptom of any importance fails of due consideration, with much statistical information in regard to it. The chapter on treatment gives a list of the drugs employed, and excellent hints as to hygiene; of course the bromides hold the first place, but the author admits that very few cases recover, and that treatment is, as a rule, only palliative. The work may be safely recommended as an admirable summing up of our present knowledge, and as a trustworthy guide in the study of the disease.

*Familiar Forms of Nervous Disease.* By M. ALLEN STARR, M.D. Ph.D. 8vo., pp. xii, 339; with illustrations. New York: Wm. Wood & Co. 1890.

"This work is not a treatise upon nervous diseases. It is a series of clinical studies of the more familiar types." Its object is "to make available to the general practitioner some of the results of later investigations, which have a direct and practical bearing upon the commoner forms of nervous disease." Such has been the author's aim in writing the work before us, a work which somewhat belies its title, for the first half of the book is entirely devoted to a consideration of the localization of disease in the brain and spinal cord. These chapters afford an excellent summing up of our present knowledge of the subject, beginning with a short review of the methods of determining the cerebral functions, with a brief account of the cerebral convolutions and the chief points in cranio-cerebral topography, and going on to describe the symptoms of disease in the various regions of the cortex, the association tracts, the base of the brain, and the cord. From Dr. Starr's previous work on the sensory tract and the speech centres, much of which has been incorporated in these chapters, we can readily judge of the character of the chapters before us; a faculty of grasping the salient points of the work of other investigators, and an admirably clear

and simple fashion of summing them up in a brief space. Withal there is somewhat more positiveness than is warranted in the most scientific dealing with the subject; witness the statement that "it is not difficult to distinguish between lesions on the base affecting the ocular nerves and lesions within the cerebral axis affecting their nuclei in the floor of the fourth ventricle." If the diagnosis is to be supported by autopsy the distinction is by no means so easy as it might seem from a study of this chapter. Nevertheless, these positive and definite assertions are what is to be desired in a work for the student and the general practitioner. Qualifications and shadings are to be added later. These chapters, too, are by no means a mere compilation of the work of original investigators. They are enriched and illustrated by a series of carefully-chosen and well-described cases, drawn chiefly from the abundant material at the author's disposal. Taken as a whole they form one of the best guides for the general practitioner for the localization of cerebral or spinal disease with which we are acquainted. For the finer points in diagnosis between sclerosis, abscess, tumor, hemorrhage, or softening he must go elsewhere, but from these chapters he can learn how to distinguish the seat of the lesion.

The second half of the book is devoted to an account of various forms of nervous disease, such as are more commonly met with, locomotor ataxia, neuritis, infantile paralysis, chorea, epilepsy, etc. Here the author has been aided by his various assistants, Drs. Petersen, Vought, Skinner, Swift, and Goodkind, who have written various chapters. These chapters are of importance, less from their descriptions of the various affections, than from the statistical information they contain drawn from Dr. Starr's clinic at the College of Physicians and Surgeons. Of these we can mention only Dr. Petersen's chapter on the ordinary forms of insanity, as the best introduction to the study of insanity that we know of, — a chapter that should be studied by every physician. Dr. Starr adds a brief but sound chapter on the treatment of neurasthenia, and one on the use of electricity, repeating his somewhat pessimistic views previously published. The formulary of the Vanderbilt Clinic and a list of cases treated at that clinic for two years are added.

*The Modern Malady, or Sufferers from "Nerves."* By CYRIL BENNETT, with a preface by HERBERT TIBBETS, M.D., F.R.C.P.E. 12mo., pp. xvii, 184. London: Edward Arnold. 1890.

This little work, somewhat amusing, and somewhat controversial, is written from the standpoint of a layman. The first half is devoted to combating the ignorance which obtains in regard to the various nervous affections which are generally lumped under the head of neurasthenia, and the author's animosities seem divided between those who say that there is nothing the matter and that the patient should be led to overcome her feelings, those who make the diagnosis of hysteria, and those who prescribe the Weir Mitchell form of treatment. Poetry and allegory are frequently used to support his views. The second part is devoted to the causes of neurasthenic conditions — heredity, imperfect social conditions, and imperfect systems of education. In these chapters there is not a little that is suggestive, often put in a somewhat fanciful form, but there is little that is new to any one who is at all conversant with modern views.

## KOCH'S REMEDY IN GENITO-URINARY TUBERCULOSIS.

THE report of cases of tuberculosis of the genito-urinary tract, from Guyon's clinic, adds additional testimony to that already accumulated as to the result of tuberculin in the treatment of tuberculosis, but the study is from an unusual class of cases, and a class which offers a field for careful observation.

There were four cases: one of periprostitis and double epididymitis; the second of cystitis and right pyelonephritis, with inflammation of the vesiculae; the third of cystitis, probably tuberculous; the fourth of cystitis and pyelonephritis. A fifth patient, with lupus of the face, but without urinary disease, was treated and reported with these cases. Some of these patients had pulmonary lesions, which presented phenomena of like character with those repeatedly observed, and need not be noticed.

On the part of the bladder, there was an increase in the frequency of micturition, and in pain during the act, which was a common but not invariable sequel of the injections, so that no diagnostic value could be attributed to it. The urine was sensibly diminished, from a fifth to a half and even two-thirds, after several inoculations; but no inference could be drawn as to the condition of the kidneys.

Albumen was usually increased in the urines that already held it, and appeared in the urines that had not previously held it, one of these cases being the case of lupus, in which all signs of urinary trouble were lacking.

In those urines in which no bacilli had been seen none were subsequently seen; but in the urines in which bacilli of tuberculosis were found the day after the first inoculation, they were still found eight days after the fifth inoculation.

Red blood globules were found in some cases which presented no idea of hæmaturia to the naked eye. It appeared in one case in which the kidneys were absolutely healthy. Casts and renal epithelium were never found.

The observations published by authors who have noticed in certain cases of pulmonary or cutaneous tuberculosis sometimes hæmaturia, often albuminuria, encouraged the idea that these symptoms would be very marked in renal tuberculosis, and that tuberculin might clear up the diagnosis in doubtful cases; but these cases of Guyon emphasize its failure from the diagnostic point of view. From the therapeutic point, there is also nothing encouraging. The enlargement of a fistula of smallest size; the appearance of tubercular nodules in a cord which appeared previously healthy; no modifications in other lesions,—such is the total.

These cases are too few to be of great value alone, but they were conducted with great care by a man who is anxious to increase his therapeutic weapons against a manifestation of tuberculosis in which little can usually be hoped. The results are singularly like those of observers in other fields, and but strengthen the conclusions already drawn: that the remedy evidently has power, but as yet, no diagnostic and little therapeutic value, has been established.

## TREATMENT OF THE CATARRHAL AFFECTIONS OF SPRING TIME.

APART from epidemics of influenza, like that through which large portions of this country have been lately passing, the severe weather of the spring time makes colds, bronchial and pulmonary affections very prevalent.

What shall be done for a cold in the head? It may not be always possible to break up a cold. Sometimes during the congestive stage, anything which will allay irritation will suffice. The person who feels a cold coming on will instantly betake himself to bed, drink a cup of hot ginger tea and make use of a snuff like that which was proposed several years ago by Dr. Ferrier:

R	Morph. sulph.	. . . . .	gr. j.
	Bismuth sub-nit.	. . . . .	ʒ iij.
	Pulv. acacie	. . . . .	ʒ i. M.

The insufflation of a little morphine at the commencement of a cold in the head is sometimes attended with very happy results.

Quinine as an abortant in commencing cold is much in use; the dose should be somewhat large; Dr. T. J. MacLagan says *ten grains*. Its efficiency is, however, rather problematical.

Doubtless, menthol is one of the best local applications in the early stages of a coryza. It may be used in the form of an ointment (menthol one part, vaseline thirty parts) or as a spray with liquid albolene. A formula which may do good service is the following: menthol, one part, liquid albolene, thirty parts. A special spray atomizer, such as is sold by all the instrument makers, is needed for the effective use of this combination. Menthol seems to limit congestion to the mucous membrane; it is often followed by a profuse flow of nasal mucus, with little sneezing.

Breathing through the nose and mouth the steam of hot camphor water, and the internal use of carbonate of ammonia, are also recommended, and there is often utility in the production of active diaphoresis. Many of late years have claimed decided benefit from full doses of antipyrin, acetanilid, phenacetin, in the onset of colds; and doubtless, these new remedies are more and more taking the place of the depressant diaphoretics.

For naso-pharyngeal catarrh and for tonsillitis, Dobell's solution, used by the hand atomizer or syringe will often prove of service. It consists of a fluid drachm and a half of strong carbolic acid, two drachms each of borax and bicarbonate of soda, two fluid ounces of glycerine, and enough water to make two pints. If the mouth and throat be quite frequently sprayed with this solution, no gargle will be needed. MacKenzie's guaiacum lozenges are much in repute for sore throat; many practitioners prefer lozenges of cubebs. There are some that have great faith in hourly drop doses of tincture of aconite for colds with febrile symptoms, especially when the tonsils are involved.

When the cold comes on in the form of a bronchitis it may be possible, at the very onset, to break it up by an emetic of ipecac or tartar of antimony, followed by profuse sweating induced by the same remedies. It is not now so much the custom as formerly to give antimonials through the dry stage of bronchitis; many physicians never prescribe them, relying on ipecac, veratrum, lobelia, and saline expectorants. In the estimation of these practitioners, tartar emetic is always a dangerous remedy, especially in children, the weak and the aged, and the benefits which are sought from this remedy can be equally well obtained from drugs which are far safer.

The citrate of potassium is a favorite remedy of Dr. H. C. Wood in acute bronchitis; his formula is, he says, the most reliable and efficient sedative cough mixture that he has ever used:

R Potass. citrat.	3 i.
Suc. limonis . . . . .	1 1/2 ii.
Syr. ipecac . . . . .	1 1/2 ss.
Syr. q. s. ad . . . . .	1 1/2 vi. M.
Sig. A tablespoonful four to six times a day.	

Another favorite expectorant with this writer is oil of eucalyptus, which may be given in five minim capsules every three hours. It is only of use after expectoration is established.

Carbonate or chloride of ammonium are valuable expectorants in all stages of bronchitis, but especially after the first or inflammatory stage has passed. The chloride is the most generally serviceable; if given rubbed up with an equal quantity of extract of licorice in some agreeable emulsion (as almond emulsion) patients will not generally complain of its unpleasantness. The dose is from five to ten grains; as its effect is transient, the dose should frequently be repeated.

The harassing cough of bronchitis will call for an occasional opiate. Probably the paregoric elixir will long continue to hold the first place among the opium preparations, where the indication is to allay cough.

A simple solution of morphia and tartar emetic long ago prescribed by Graves (though, perhaps, too little known) will sometimes in the dry stage of bronchitis in robust adults, suffering from a constant, dry, teasing cough which forbids any rest, give notable relief in the course of a few hours; the formula is as follows: morphia sulph., tartar emetic, of each one grain, syrup, water, of each six fluid drachms. The dose is a teaspoonful every hour till the cough is relieved.

There is not unanimity in regard to counter-irritation in this disease; but few, however, object to the mustard poultice, which certainly often markedly relieves the dyspnoea and oppression. In the bronchitis of early life, early resort is had to the jacket poultice of luscious meal, which is made to envelop the whole chest, and is frequently renewed.

In infantile catarrhs there is always fear lest the bronchitis shall become capillary, or invade the lungs. Here, early stimulation is called for. Alcohol in some form (wine, brandy, whiskey), best fulfils the indication to support the heart and the vital forces. Aconite, antimony, veratrum are regarded as too depressing; at the most, an emetic of ipecac is now and then permitted when the bronchi are engorged. Children, in these diseases, will often bear large quantities of brandy, which, if there be signs of approaching heart failure, may be combined with digitalis. A favorite method with some practitioners, is to add ten or fifteen drops of tincture of digitalis to the alcoholic potion which is designed to be given through the day, and which, for a child of five years old, may be a four ounce mixture of equal parts of brandy and sweetened water. Of this mixture, a teaspoonful every hour or every half hour may be required. The whiskey or brandy is sometimes advantageously given with milk and egg in the form of punch. There are those who think well of small fly-blisters over the principal seat of the disease.

Dr. H. C. Wood speaks of a heroic method to which he has sometimes resorted in suffocative bronchitis; the child is stripped and put first into a hot, then into a cold bath; ladfuls of hot water are dashed over the chest, then sudden douches of cold water are resorted to; powerful inspiratory efforts are thus provoked, and the most desperate cases are sometimes made better if not saved.

The treatment of pneumonia, it is well-known, has undergone quite a revolution in the past twenty-five years; the antiphlogistic methods formerly in vogue, have been abandoned; a stimulating and supporting régime is generally enforced. Formerly, it was the custom to treat this disease from the first with liberal doses of tartar emetic; at the present day few well-instructed medical men rely much upon this medication in the therapeutics of pneumonia. Statistics have proved again and again that pneumonia is a self-limited disease, that it does not do better with tartar emetic than without it, and at the most, only certain symptoms, as dyspnoea, may be favorably modified by the administration of small doses of the antimonial.

In fact, the microbial theory of pneumonia is coming more and more to the front, and the fact is recognized that the predominant indication—in the absence as yet of any known parasiticide medication—is to sustain the vital forces in their struggle with the bacterial enemy.

#### A BILL PROVIDING FOR THE REGISTRATION OF PHYSICIANS IN MASSACHUSETTS.

WE print in this issue a bill which has been reported to the Massachusetts House of Representatives by the Committee on Public Health. Compared with many laws regulating medical practice in other States, and with bills previously discussed in this State, it has the merits of conciseness and simplicity. No medical board of examiners is created nor medical society authorized to give permission to practise, the bill simply requiring that any one who intends to practise medicine shall appear before a city or town clerk, and describe, among other facts, his degree, or, if he have no degree, what preparation or experience he has had in medicine. The register is to be open to public inspection, and a list of persons so registered is to be published annually by the State Board of Health.

The bill has recently, on technical grounds, been referred back to the Committee.

#### MEDICAL NOTES.

**PROTEST AGAINST AN AIR GARDEN.**—The New York Academy of Medicine has protested against the construction of an "air garden," as the projectors call it, to consist of plants and pavilions on top of the Croton reservoir at Forty-second street.

**THE COMMENCEMENT SEASON IN CINCINNATI** has just closed with the following numbers in the graduating classes: Medical College of Ohio, 94; Miami Medical College, 27; Cincinnati College of Medicine and Surgery, 25; College of Pharmacy, 29; Dental College, 75; Pulte Medical College, 29; Woman's Medical College, 2.

**THE TRANSACTIONS OF THE TENTH INTERNATIONAL MEDICAL CONGRESS.**—The Committee on Publication have given notice that the first volume of the transactions, containing the "general" part, is now obtainable. Members of the congress should apply to August Hirschwald in Berlin. The postage on the volume is about twenty-five cents.

**THE UBIQUITY OF THE TUBERCLE BACILLUS.**—In 1888, says the *Wiener medicinische Presse*, Schnürer discovered accidentally that the water which had been used to rinse the grapes bought of a Viennese street peddler, if injected into the abdominal cavity of guinea-pigs, always caused tuberculosis. This suggested the advisability of washing fruit, and also, by a different method, agreed with the results of Cornet, who found the bacilli in many different places in a city.

**PROSTITUTION IN BERLIN.**—The number of women under police control (including medical supervision) in Berlin in 1875 was 2,140; at the end of 1890 it had risen to 4,068.

**TYPHOID FEVER IN THE FRENCH ARMY.**—During 1890, the typhoid mortality in the whole French army was forty-nine per cent. less than in the previous year. In the military Government of Paris the diminution was seventy-five per cent. This satisfactory result is attributed to the measures adopted by the Minister for War for the purification of the water supply to barracks.

**THE PRACTICE OF MEDICINE BY WOMEN IN GERMANY.**—In the German Reichstag, on March 11th, Herr Schröder urged, in the course of a discussion in favor of the admission of women to the liberal professions, that it was the duty of the Government to pave the way for women to practise medicine. Dr. Orterer opposed this view. The House declared against the petition.

**CHLORALIMIDE.**—That two drugs should have almost the same name, is, to say the least, unfortunate. *Merck's Bulletin* points out that chloralimide should not be confounded with "chloralamide." Chloralimide is in colorless, inodorous, and insipid, long crystalline needles, insoluble in water, readily soluble in alcohol, in ether, in chloroform, and in oils. It is stable under the influence of light, air, and heat. The dose is the same as that of chloral hydrate. It may be administered in wafers, in pills, in alcoholic solutions, or in an oily emulsion.

**PECULIARITIES OF THE TARIFF.**—The *Pharmaceutical Era* says that under the McKinley tariff, "mineral waters, all not artificial," are admitted free; but in the same tariff, under the liquor clauses, it is recited that "all mineral waters and all imitations of natural mineral waters, and all artificial mineral waters not specially provided for," shall be dutiable, etc. The collector says that while he realizes that the intention was to admit natural mineral waters free, and that he perceives that the addition of a comma to the last phrase of the foregoing sentence would make the whole consistent with that idea, he is nevertheless compelled to read literally, and he therefore imposes a duty upon natural mineral waters. Like the Mikado, he deplors "the slovenly way in which these laws are drawn," but is equally powerless to stay their execution. The rulings remind one of the decision which the drunken Irishman came to, as he staggered home: "Av me woife's waitin' up for me, I'll bate her!" said he, "and if she's gone to bed, I'll bate her!" Then after a little reflection he added, "begob, I'll bate her anyway!"

**ACT TO PREVENT UNPROFESSIONAL CONDUCT IN ARKANSAS.**—A law has been passed in Arkansas providing that if any physician practising by virtue of a license issued under the laws of the State, is guilty of unprofessional conduct, his license may be revoked

by the board of medical examiners, after trial. After a year he may be reinstated if the examiners think that he has reformed. "Unprofessional conduct for the purposes of this act shall be held to be: The procuring, or aiding, or abetting in the procuring of criminal abortion; Employing or using what are known as cappers, steerers or drummers, or the subsidizing of hotels or boarding-houses to procure practice; The obtaining of any fee on the assurance that a manifestly incurable disease can be permanently cured; The wilfully betraying a professional secret to the detriment of a patron; All advertising of medical business in which untruthful and improbable statements are made; All advertisement of any medicine or means whereby the monthly periods of women can be regulated or the menses re-established; Conviction of any offence involving moral turpitude; Habitual drunkenness."

Among the curious cases which came under our notice, says a correspondent of the *China Missionary Medical Journal*, is the following one of protracted labor, where the father of the woman, seeing that both mother and child were in danger, seized a sharp iron hook, resembling those on which the butchers hang dressed beef, but here used in the native steelyard. Introducing this into the scalp of the child, he succeeded in saving both mother and child. Nearly the whole scalp was detached in three places from the skull. The father walked twelve miles to the hospital with the child in his arms. The wound was sutured with silver wire, and to-day the infant is a vigorous boy.

**NEW DRUGS AND OLD REMEDIES.**—In connection with the method of Brown-Sequard, and the introduction of new remedies derived from seminal fluid, a correspondent of the *British Medical Journal* shows that the idea is a very old one, by introducing an old book published in 1661, in which the author says: "The testes being virous, especially after coiture are hard and not easily connected, those of lambs are not disconnected, and help decayed bodies and cause manly vigor. The testicles of cocks, fed with a serose meat steeped in milk, are desired by the delicate as promoters of vigor, and some say that being kept from the hens they will every day add so much weight to the body, as the testes themselves are in weight. The right testicle of an ass causeth youthful vigor, being drunk in wine, or worn, so the foam taken in a red cloth, or inclosed with silver, so the ashes of the genital. If they are kept with salt, and powdered and put upon drink, they help the falling sickness."

**A PROFESSIONAL MISTAKE.**—The *Medical Press* relates that an American practitioner was walking along the Unter den Linden in Berlin late at night in deep reflection, when suddenly a suspicious looking individual hustled by, closely touching him. The former with the natural ingenuity of his race, immediately felt for his watch, found it was gone and started in pursuit of the robber. The suspicious individual fled through the Brandenburg Gate into the Thiergarten, closely pursued by the American, who kept loudly

shouting, "Put up that watch." Near the Victory Column the robber was caught by his pursuer and compelled to deliver up the watch, after which he was released. The delighted practitioner, feeling exceedingly proud of his achievement, returned to his hotel. But the first thing he saw on entering his bedroom was his watch lying on the table! He had forgotten to take it with him when he went out. Next morning all the papers published the story of a robbery in the Thiergarten; a French doctor, it was stated, had been pursued by a burly, powerful thief, who attacked and robbed him of his valuable watch. History fails to add the sequel to this story.

#### NEW ENGLAND.

**THE INSPECTION OF MILK.**—The Committee on Agriculture has reported a bill to the Massachusetts Legislature relating to the inspection and sale of milk, so that the farmer who sells milk showing by analysis less than thirteen per cent. of solids, even if he can prove the same to be the natural product of a healthy cow, shall be incriminated. Any producer of milk selling in open market, shall be entitled to have from one to three samples of his milk analyzed by the State Board of Health without expense to him.

**THE CHRONIC INSANE.**—The Public Charities' Committee has reported a bill authorizing the governor and council to appoint three commissioners on the erection of buildings, on the lands recently purchased in Medfield and Dover, for an asylum for the chronic insane, for the accommodation of one thousand patients, at an expense not exceeding \$500,000. The bill authorizes the issuing of script or certificates of indebtedness to meet the same.

#### NEW YORK.

**UNIVERSITY OF THE CITY OF NEW YORK.**—The annual commencement of the Medical Department of the University of the City of New York was held at the Metropolitan Opera House on Tuesday evening, March 24th, and at the same time the fiftieth anniversary of the school was celebrated. The principal address of the evening was made by the Rev. Dr. Henry Van Dyke. There was a graduating class of 203, and the valedictorian was Francis S. Kennedy.

**INFLUENZA.**—While the gripe may be said to have again visited New York, it is in a comparatively mild form, and the cases are much less numerous than during the epidemic of last year. The weekly death-rate is always comparatively large at this season, but up to the present it has been somewhat smaller than the average for the past five years at this time of the year.

**SQUINT CORRECTED BY AN OPERATION FOR DEFLECTED SEPTUM.**—At a meeting of the Section on Laryngology and Rhinology of the Academy of Medicine, held March 24th, Dr. F. J. Quinlan reported a case of convergent squint corrected by a modified Adams operation for deflected septum.

## Miscellany.

### THE SUBCUTANEOUS USE OF ANILINE DYES.

A SHORT time ago Moseitig published his method of treating malignant growths by the injection of aniline dyes,<sup>1</sup> and called attention to the non-poisonous nature of the aniline compounds at present obtainable.

Stilling, to whom is largely due the introduction of different pyoktanins, points out a possible danger in the subcutaneous use of those dyes which are comparatively soluble in water.<sup>2</sup> These substances if allowed to reach the blood-current in too large a quantity, may stain and injure the blood-corpuscles. Some of Moseitig's failures may have been due to this accident. Malachite-green and methyl-blue are more soluble than methyl and ethyl-violet, the latter being soluble in about 1-1550, and consequently safe to use as a powder on an open wound, but hardly safe to inject in a concentrated solution subcutaneously. The best preparation for the latter purpose is a substance with a long name, called for short ethylpyoktanin. The author also proposes in the treatment of malignant growths that the arteries which supply the tumor should be first tied, so as to render the growth temporarily anæmic, and that while in this condition it should be thoroughly permeated with the dye-stuff.

### BACTERIA AND EXHAUSTION.

It is generally believed that one is most liable to acquire infectious disease if exhausted when exposed to it. This belief is strengthened by a communication published in the *Deutsche medicinische Wochenschrift*, No. 34, 1890,<sup>3</sup> and made to the Société de Biologie by Roger and Charrin. It refers to experiments in which animals were forced to undergo severe muscular exertion, and were thereafter found to show seven or eight times as great vulnerability and susceptibility to bacteria as in normal circumstances.

### BACILLI IN TUBERCULIN.

A FEW weeks ago Liebmann reported that he had found tubercle bacilli in the blood of patients undergoing the Koch treatment. Later he reported that he had found bacilli in tuberculin, and a report from Russia announced that living organisms of undetermined character had been found in it.

Influenced undoubtedly by these rumors, Libbertz has issued a proclamation<sup>4</sup> as follows:

In the preparation of tuberculin it cannot always be avoided, that in some cases a few tubercle bacilli get into the fluid. But these bacilli have been killed by long boiling, and are therefore entirely harmless. To be sure Koch said in his last publication that bacilli after being killed, caused suppuration if introduced under the skin. But this applies only to washings from cultures, and consequently to bacilli in large quantities. Occasional ones excite no local nor general reaction. It would be impossible for them to get into the circulation, unless they were injected directly into a vessel. Tuberculin is made of a pure culture of tubercle bacilli,

in it consequently are no other bacteria. Of course, it is possible that in closing or opening the bottle some organisms from the air may get in, but in that case the microbes would be almost always of a harmless variety. These organisms would not be able to multiply on account of the large percentage of glycerin. Tuberculin has always an alkaline reaction.

### CHANGES IN THE BLOOD AND URINE OF THE INSANE.

DR. JOHNSTON SMITH<sup>1</sup> has made a prolonged and elaborate investigation into blood-changes in melancholia, epilepsy, general paralysis, and secondary dementia. The direct evidences of blood-changes are as follows: In the insane, marked diminution of hæmoglobin—greatest in secondary dementia; marked decrease in the number of red blood-corpuscles, especially in secondary dementia also; unusual density of the blood plasma, particularly in secondary dementia, and in epilepsy during the convulsive attacks. Indirect evidence of blood-change is found in the results of examination of the urine. The urine is much in excess of the healthy standard in general paralysis. Uric acid is increased in the excretion of the insane. Creatinin is increased in general paralysis and secondary dementia. Phosphoric acid is slightly increased in epilepsy. Presumptive evidence of changed blood condition Dr. Smith finds in the profuse sweats of general paralysis, the rapidity with which the wounds of epileptics heal, their oily skin and their peculiar odor. With regard to the relation of these blood-changes to the cerebral diseases, the writer concludes that in some forms of mental disease the blood is imperfect *ab initio*, and fails to supply materials for the growth and development of the brain; whilst in other forms of mental disease the blood-change is secondary to organic disease, and the brain of the unstable cannot resist the influence of its diseased blood supply.

### STUPOROSE INSANITY FOLLOWING HYPNOTISM.

MR. NOLAN reports this case in the *Journal of Mental Science*, for January.<sup>2</sup> The patient was a soldier, with neurotic taint, who, on being promoted to the rank of lance-corporal, felt unequal to his new duties, and abandoned himself to sexual and alcoholic excesses. While in a state of consequent nervous instability he voluntarily submitted to being hypnotized by an experimenter. Profound hypnosis was rapidly induced by gazing at a bright object. From this state the patient did not completely emerge until the lapse of nearly four months. When brought to the asylum he was in a stuporose condition, with eyelids blinking, nostrils expanded, lips pursed and tremulous, hands rhythmically striking the thighs, etc. Neuro-muscular hyperexcitability was subsequently noted, and still later Erlemeyer's "contracture by antagonistic distension" developed. Throughout the period of stupor the patient was disturbed by a recurring visual hallucination—an old hag, seemed to rush towards him. This hallucination arose during the condition between sleeping and waking, and persisted for some time after as-

<sup>4</sup> *Deutsche Medicinische Wochenschrift*, March 12th.

<sup>1</sup> *Practitioner*, March 1, 1891; and *Journal of Mental Science*, October, 1890.

<sup>2</sup> *British Medical Journal*, March 7.

sociated delusions had subsided. Sleeplessness was successfully treated by the prolonged use of sulphonal. Recovery was complete at the end of five months.

### LEUCOCYTES IN DISEASE.

DR. CASTELLINO<sup>1</sup> communicates the result of his observations upon the white corpuscles of the blood in different morbid conditions. His researches, which were conducted in the laboratory of the medical clinique in Genoa, have occupied three years of observation on more than a hundred patients. His conclusions are as follows: (1) Along with the destruction of the red globules of the blood there is an increase in the white globules in the following diseases, which are arranged in the degree of the number of the said leucocytes: Pneumonia, erysipelas, scarlatina, pleurisy and typhoid fever. (2) These leucocytes rise in quantity with the temperature, and, except in the case of pneumonia and erysipelas, begin to diminish with the decline of the fever. (3) In these two last diseases the leucocytes only begin to diminish several days after the crisis is past. (4) In acute infections there is a predominance of small white globules, which are finely granular with one nucleus (the leucoblasts of Löwit). (5) In leukaemia and chronic infectious diseases (such as syphilis, malaria, and lead-poisoning), there is a predominance of the large leucocytes with coarse granulations, having many nuclei without nucleoli (erythroblasts of Löwit). Many of these granules answer to the chemical and microscopical tests of fatty substances.

### TESTING FOR IRON IN ORGANS.

ZALESKI<sup>2</sup> gives a simple method for detecting histologically the presence of iron in organs. Small pieces of the organ are hardened first in sixty-five per cent. alcohol, and then in ninety per cent. alcohol, to which a few drops of yellow ammonium sulphide are added. In twenty-four hours, if iron be present, the tissue has a greenish appearance, and on making a section the exact distribution of the particles of iron sulphide is readily detected by the color reaction.

### THE CONTAGION OF WHOOPING-COUGH.

EIGENBROT<sup>3</sup> has studied the spread of whooping-cough, and comes to the conclusion that the disease is often carried through persons suffering from an abortive attack, often so mild as not to arouse suspicion of its character, especially as the whoop is often entirely lacking. One of the peculiarities of these abortive attacks is the exacerbation of the cough at night. He considers that a genuine attack of whooping-cough renders the individual immune against the complete disease, but not against abortive attacks; and *vice versa* a person who has had nothing but abortive attacks may have the disease. Adults may carry the infection without suspecting the nature of their cough. In two cases the incubation period seemed to be eleven days.

### CHLORAL AS A COAGULANT.<sup>1</sup>

ACCORDING to Dr. Marc Sée hydrate of chloral possesses the property of coagulating blood and serous fluids, and may be made to replace the iodine solution generally injected into hydroceles. He himself has treated two hundred hydroceles with chloral without the occurrence of any accident. He employs for this purpose a ten per cent. solution, an ounce of which is injected all at once, or very slowly, into the sac. Two or three days afterwards a large effusion of fluid into the tunica takes place, but is soon entirely reabsorbed. Where the hydrocele wall is much thickened injections of chloral, or, indeed, of any kind, are useless, and reconre must be had to free incision. The chloral solution above referred to may be repeatedly injected, with advantage, into the neighborhood of varicose veins, as it causes the blood gradually to coagulate, and the veins to contract. Some trials have also been made with chloral as an injection into vascular tumors, but hardly sufficient to warrant any definite report.

### EFFECT OF HIGH TEMPERATURE ON DISINFECTANTS.

DR. ADOLPH HEIDER gives an account of his experiments on the effect of a high temperature in increasing the power of disinfectants.<sup>2</sup> Anthrax spores subjected to five per cent. carbolic acid at the ordinary temperature of the room were not destroyed in thirty-six days, whilst when the temperature was raised to 55° C., a similar carbolic acid solution killed these spores in from one to two hours. With five per cent. of sulpho-carbolic acid half an hour was sufficient, with three per cent. one hour, with a five per cent. emulsion of creasote two hours. Weaker solutions of these substances were not very effective in killing the spores until a temperature of about 75° C. was reached, in which case five per cent. carbolic acid killed the spores in three minutes, three per cent. in fifteen minutes, one per cent. in two to two and a half hours; five per cent. of sulpho-carbolic acid in one minute, three per cent. in ten minutes; five per cent. creasote emulsion in five minutes, three per cent. in fifteen minutes. Strong acids and alkalis had also their germicidal properties increased by the higher temperature, but the actions of creolin, pyoktanin, and lime water were all considerably interfered with by the higher temperature.

### THE PREPARATION OF "MADRAS VACCINE PASTE."

THE *Indian Medical Record* of January 1st, gives the following account of the preparation of this paste:<sup>3</sup>

In preparing the calf by shaving and washing before inoculation, the soap used should not contain any antiseptic, for otherwise the vitality of the lymph is endangered. About the fifth day after the primary operation, most of the vesicles will be ripe for further treatment. In collecting the vesicles every particle of each must be carefully removed. This is done best with an ordinary bleeding-lancet, with the point

<sup>1</sup> *Lancet*, February 11, 1891.

<sup>2</sup> *Zeitschr. f. phys. Chem.*, xiv.

<sup>3</sup> *Zeitschr. für klin. Med.*, B. 17, H. 6.

<sup>4</sup> *British Medical Journal* from Centrallid., f. Bakt. u. Parasit., February 21st.

<sup>5</sup> *London Medical Recorder*, February 20th.

broken off square. The index and thumb of the left hand are firmly pressed on the skin on each side of the vesicle, which is then detached with one sweep of the lancet. If this is properly done, no blood appears. The vesicle-pulp is collected in the glass pan of an apothecary's scales, and weighed. The pulp is then placed in a small glass or agate mortar, and worked up until absolutely homogeneous. Anhydrous lanoline of the purest quality obtainable is then added to the pulp in proportion of from four and a half to ten times its weight, according to the strength desired, and the whole pounded up together. When thoroughly mixed, the paste may be stored in convenient receptacles of glass or earthenware and sealed up. Specially prepared earthenware pots are made by the Madras School of Arts, with screw-tops. It must be remembered that the living vaccine-germ perishes at a temperature of 140°, though, if exposed for long to a temperature considerably lower than this, its destruction will ensue. The preservative action of the lanoline minimizes this danger. The value of the preparation for use in tropical climates will, therefore, be understood. Sunlight is inimical to its preservation. The paste is applied much in the same way as ordinary lymph, a narrow silver blade, slightly curved at the end, being best for its abstraction from the jar. Thirty grains are said to be sufficient to inoculate thirty persons at four insertions each. Completely satisfactory results have been obtained from the use of the paste.

## PRESCRIPTIONS.

**SALICYLATE OF MERCURY.**—For hypodermic injection Vacher<sup>1</sup> uses the following solution:

R Hydrag. chloridi corrosiv. . . . . 1 part.  
Sodii salicylicæ . . . . . 2 parts.  
Aque destil. . . . . 100 parts. M.

In this solution each cubic centimeter contains one centigramme of salicylate of mercury. For use by the mouth a 1-1000 to 1-5000 solution should be used.

**A POWDER FOR DYSPEPSIA.**—Dujardin-Beaumez<sup>2</sup> uses the following powder for painful dyspepsia and gastralgia:

R Bismuth subnit. }  
Magnesie }  
Crete prep. } . . . . . 53 3 iiss.  
Calcii phosphatis } . . . . . M.

Divide in pulv. No. XL. Sig. One powder before each meal.

**PRURITUS HEMALIS.**—Corlett recommends the following topical applications in "winter itch":

R Resorcin . . . . . 3  
Glycerin . . . . . 1  
Aque, ad. . . . . 1  
Sig. Apply.

R Menthol . . . . . 1  
Glycerin . . . . . 1  
Aque, ad. . . . . 1  
Sig. Apply.

R Icthyol. ammon. sulph. . . . . 3 j. to iil.  
Glycerin . . . . . 1  
Alcohol } . . . . . 5  
Aque } . . . . . 5  
Sig. Apply.

# A BILL TO REGULATE THE PRACTICE OF MEDICINE IN MASSACHUSETTS.

THE Committee on the Public Health reported in the House March 24th, this bill to regulate the practice of medicine by the registration of practitioners:

**SECTION 1.** Every person now engaged in the practice of medicine or surgery, or the healing art, in any form except dentistry, as a business or occupation, shall on or before October 1, 1891, and every person hereafter shall before commencing such practice, register in the office of the clerk of the city or town where he or she intends to commence such practice, in a book kept by said clerk, with book shall be open to the public inspection, his or her name, residence, and place of birth, previous occupation and residence, together with the name of the college or institution, if any, from which he or she has received a medical degree of any kind, and the date of issue and description of said degree, and if not a graduate of any college or institution, what special study, work or experience he or she has had as preparation for such practice. The person so registering shall subscribe by oath or affirmation before a person duly qualified to administer on the under the laws of the Commonwealth an affidavit containing such facts as are required by this act, which, if wilfully false, shall subject the affiant to conviction and punishment for perjury. The city or town clerk shall receive a fee of twenty-five cents for such registration as compensation, to be paid by the person so registering.

**SECT. 2.** Whoever, not being registered as aforesaid, shall advertise himself or herself as such practitioner, by the exposure of a business card, doorplate or sign of any kind to public view on a public highway, which may operate to lead any person to believe that the person so advertising himself or herself is so entitled to practice, shall be punished by a fine of not less than fifty dollars and not more than one hundred dollars for the first offence, and for each subsequent offence by a fine of not less than one hundred dollars nor more than five hundred dollars, or by imprisonment for not less than thirty days nor more than ninety days, or both.

**SECT. 3.** Each city and town clerk shall prepare and forward annually, on or before December 1st, to the State Board of Health a list of all persons so registered in his office, together with such other information as is called for under Section 1 of this act, and the State Board of Health shall include the same in their annual report to the Legislature.

**SECT. 4.** Nothing in this act shall apply to commissioned medical officers of the United States Army, Navy or Marine Service, or to any legalized physician or surgeon called in consultation from any other State or Country.

## RECORD OF MORTALITY FOR THE WEEK ENDING SATURDAY, MARCH 21, 1891.

## Address.

AMERICAN INVENTIONS AND DISCOVERIES  
IN MEDICINE, SURGERY AND PRACTICAL  
SANITATION.<sup>1</sup>BY DR. JOHN S. BILLINGS, *United States Army.*

In connection with this celebration of a century's work of the American Patent System, I have been requested by the Advisory Committee to prepare a brief paper upon inventions and discoveries in medicine, surgery and practical sanitation, with special reference to the progress that has been made in this country in these branches of science and art.

It would be impossible to present on this occasion such a summary as would be of any special interest or use, of the progress which has been made in medicine and sanitation during the century, either by the world at large or by American physicians and sanitarians in particular; and I shall therefore confine my remarks mainly to the progress which has been made in these branches in connection with mechanical inventions and new chemical combinations, devised by American inventors, — which will require much less time.

The application of the patent system to medicine in this country has had its advantages for certain people, has given employment to a considerable amount of capital in production (and to a much larger amount in advertising), has contributed materially to the revenues of the government, and has made a great deal of work for the medical profession.

So far as I know, but one complete system of medicine has been patented in this country, and that was the steam, Cayenne pepper and lobelia system, — commonly known as Thomsonianism, — to which a patent was granted in 1836. The right to practise this system, with a book describing the methods, was sold by the patentee for twenty dollars, and perhaps some of you may have some reminiscences of it connected with your boyish days. I am certain I shall never forget the effects of "Composition Powder," or of "Number Six," which was essentially a concentrated tincture of Cayenne pepper, and one dose of which was enough to make a boy willing to go to school for a month.

From a report made by the Commissioner of Patents in 1849, it appears that eighty-six patents for medicines had been granted up to that date; but the specifications of most of those issued before 1836 had been lost by fire. The greater number of patents for medicines were issued between 1850 and 1860. The total number of patents granted for medicines during the last decade (1880-1890) is 540.<sup>2</sup>

This, however, applies only to "patent medicines," properly so-called, the claims for which are, for the most part, presented by simple-minded men who know very little of the ways of the world. A patent requires a full and unreserved disclosure of the recipe, and the mode of compounding the same, for the public benefit when the term of the patent shall have expired; and the Commissioner of Patents may, if he chooses, require the applicant to furnish specimens of the composition and of its ingredients, sufficient in quantity for the purpose of experiment. The law, however, does not require the applicant to furnish patients to be

experimented on, and this may be the reason why the commissioner has never demanded samples of the ingredients. By far the greater number of the owners of panaceas and nostrums are too shrewd to thus publish their secrets, for they can attain their purpose much better under the law for registering trade-marks and labels, designs for bottles and packages, and copyrights of printed matter, which are less costly, and do not reveal the arcanum.

These proprietary medicines constitute the great bulk of what the public call "patent medicines."

The trade in patent and secret remedies has been, and still is, an important one. We are a bitters- and pill-taking people; in the fried pork and saleratus-biscuit regions the demand for such medicines is un-failing, but everywhere they are found. I suppose the chief consumption of them is by women and children, — with a fair allowance of clergymen, if we may judge from the printed testimonials. I sampled a good many of them myself when I was a boy. Of course, these remarks do not apply to bitters. One of the latest patents is for a device to wash pills rapidly down the throat.

According to the Census of 1880 there were in the United States 592 establishments devoted to the manufacture of drugs and chemicals, the capital invested being \$28,598,458, and the annual value of the product \$38,173,658, while there were 563 establishments devoted to the manufacture of patent medicines and compounds, the capital invested being \$10,620,880, and the annual value of the product \$14,682,494.<sup>3</sup>

A patent automatic doctor, on the principle of "put a quarter in the slot and take out the pill which suits your case," has been proposed, but this patent is said to be of Dutch and not of American origin. The idea of this may have come from Japan, for an old medicine case from that country, which I possess, has four compartments filled with pills, and the label says that those in the first compartment are good for all diseases of the head, those in the second for all diseases of the body, those in the third for all diseases of the limbs, and those in the fourth are a sure vermifuge.

From the commercial and industrial point of view the great importance of patent and proprietary medicines is connected with advertising. The problem is to induce people to pay twenty-five cents for the liver-encouraging, silent-perambulating, family pills, which cost three cents. Some day I hope that the modern professional expert in advertising will favor us with his views as to the nature and character of those people who were induced to buy Jones's liver pills or Slow's specific by means of the huge display of these names on the sides and roofs of barns and outbuildings, which display forms such a prominent feature in many of our American landscapes, as seen by the traveller on the railway. I suppose there must be such people, for I have a high estimate of the business shrewdness of the men who pay for these abominations. I should also like to know how much a farmer gets for allowing his buildings to be thus defaced. He must be hard-up; indeed such a display indicates that the place is probably mortgaged and that the poor man is heavily in debt.

Even the soap advertisers are not as guilty as the nostrum-makers, in this particular style of nuisance, although they far exceed the latter in viciousness when it comes to applying art to ignoble purposes. The

<sup>1</sup> Paper read at the celebration of the beginning of the second century of the American Patent System, held at Washington, D. C., April 8-16, 1891.

<sup>2</sup> For these figures, and other data used in this paper I am indebted to my friend Mr. H. H. Bates, Chief Examiner in the Patent Office.

<sup>3</sup> See the *Lancet*, October 5, 1889, p. 683.

connection between progress in medicine and soap advertisements may not be clear to you, but it exists nevertheless, for many of these soaps make work for the doctors by producing skin troubles.

Upon the whole I should think that the number of people who would take some trouble to avoid purchasing an article which is thus advertised must be rapidly increasing, so that such displays will soon be no longer profitable. The great importance of advertising does not relate to the placard or chromo business, but to its relations to periodical literature, — to the daily and weekly press and the monthly magazines and journals.

To the establishment and support of some of our newspapers and journals, medical as well as others, these proprietary and secret medicines, cosmetics, food-preparations, etc., have no doubt contributed largely.

I am sorry to say that I have been unable to obtain definite information as to the direct benefits which inventions of this kind have conferred on the public in the way of cure of disease or preventing death. Among the questions which were not put in the schedules of the last census were the following, namely: Did you ever take any patent or proprietary medicine? If so, what and how much, and what was the result? Some very remarkable statistics would no doubt have been obtained had this inquiry been made. I can only say that I know of but four secret remedies which have been really valuable additions to the resources of practical medicine, and the composition of all these is now known. These four are all powerful and dangerous, and should only be used on the advice of a skilled physician. Most of such remedies have little value as curative agents, and some of them are prepared and purchased almost exclusively for immoral or criminal purposes.

In France the sale of secret and patent medicines is not allowed unless they have been examined and approved by the National Academy of Medicine, and the same general rule holds good in Italy and Spain.

The Japanese have followed the French method, and their experience is interesting. The Central Sanitary Bureau established a public laboratory for the analysis of chemicals as a medicine. The proprietors of each of such medicines were bound to present samples, and the names and proportions of the ingredients, directions for its use, and explanations of its supposed efficacy. According to a report in the *British Medical Journal*, during the first year there were 11,304 applicants for license to prepare and sell 148,091 patent and secret medicines. Permission for the preparation and sale of 58,638 different kinds were granted, 8,592 were prohibited, 9,918 were ordered to be discontinued, and 70,943 remained to be reported on. The great majority of those which were authorized were of no efficacy, but few being remedial agents; but their sale was not prohibited, as they were not found to be dangerous to the health of the people.\* I do not vouch for these figures, which throw our records entirely in the shade.

In 1849 a special committee of the House of Representatives reported to the House a bill to prevent the patenting of medicines, accompanied by a report. This bill provided that after the passage of the act, letters patent shall not be granted for any article whatever as a medicine, provided that this shall not apply to machines, instruments or apparatus. When

the matter came before the House for consideration the bill was laid on the table.<sup>6</sup>

You are all aware that the great majority of the medical profession consider it to be improper and discreditable for a physician to patent a remedy. The Medical Code of Ethics declares that it is derogatory to professional character "for a physician to hold a patent for any surgical instrument or medicine; or to dispense a secret nostrum whether it be the composition or exclusive property of himself or others. For if such nostrum be of real efficacy, any concealment regarding it is inconsistent with beneficence and professional liberality; and if mystery alone give it value and importance, such craft implies either disgraceful ignorance or fraudulent avarice. It is also reprehensible for physicians to give certificates attesting the efficacy of patent or secret medicines, or in any way to promote the use of them." Like all legislation this is a formal declaration of the customs of the profession, which customs are of great antiquity. The principle upon which it is founded is thus expressed by Lord Bacon: "I hold every man a debtor to his profession; from the which, as men of course do seek to receive countenance and profit, so ought they of duty to endeavor themselves by way of amends to be a help and ornament thereunto."

The rule, however, is not always adhered to by physicians, the most notable exception having been, perhaps, the use of Koch's lymph before its composition was revealed. As regards the patenting of surgical instruments and apparatus, the opinion of the great majority of physicians is in accordance with the rule just stated, but there are some who question its propriety, although they obey it — and there are few who would not use a patented instrument in a case to which they thought it was applicable.

The total number of surgical instruments and appliances patented during the past decade has been about 1,200, the patents having been in almost all cases taken out by manufacturers. With these may be classed dentists' tools and apparatus, of which about 500 have been patented during the last ten years, and in this field of invention the United States leads the world. The same may be said with regard to artificial limbs, of which our great war gave rise to many varieties.

As you know, the law prescribes that a patent may be given for a "new and useful art, machine, manufacture, or composition of matter." I used to think that the word "useful" in this law had its ordinary meaning, and, therefore, wondered exceedingly as to why the Patent Office examiners allowed patents to certain things which came under my notice. One day, however, I received an article from the Patent Office, with the request for a report as to whether it was useful in the sense in which that word was used by the Office, namely, "not pernicious or prejudicial to public interests — capable of being used" — and then for the first time I understood one of the first principles of the patent law of the United States, that is, that it does not take into consideration the degree of utility in the device, or, in other words, that "useful" means "harmless."

If a patent is granted to a medicine, it must be as a composition of matter as a special article of manufacture. The practice of the Patent Office in these matters is not generally understood. It does not now

\* *Brit. Med. Jour.*, July 3, 1880, vol. II, p. 21.

<sup>6</sup> *Congressional Globe*, March 3, 1849, p. 697.

consider that medical prescriptions are inventions within the meaning of the law, or that a mere aggregation of well-known remedies to obtain a cumulative effect is a patentable composition of matter. A certain number of claims for government protection in the form of patents or trade-marks are made for medical compounds or for apparatus, under false pretences; that is to say, the claim is for a new remedy for rheumatism or dyspepsia, or displacement, with a warning against their use under certain conditions, the real design being that they are to be used under precisely these conditions in order to procure abortion, etc. These are sometimes difficult cases for the Patent Office to treat properly, for the law does not allow a large discretion for refusal on mere suspicion, and where there is ostensible and possible utility (in the Patent Office sense) it can hardly reject the claim on the ground that the invention *might* be used for immoral purposes.

I said in the beginning that I cannot, on this occasion, give any sufficient account of the progress of invention and discovery in medicine and sanitation during the century just gone. The great step forward, which has been made, has been the establishment of a true scientific foundation for the art upon the discoveries made in physics, chemistry and biology. One hundred years ago the practice of medicine, and measures to preserve health, so far as these were really efficacious, were in the main empirical—that is, certain effects were known to usually follow the giving of certain drugs, or the application of certain measures, but why or how these effects were produced was unknown. They sailed then by dead-reckoning, in several senses of this phrase.

Since then not only have great advances been made by a continuance of these empirical measures in treatment, but we have learned much as to the mechanism and functions of different parts of the body, and as to the nature of the causes of some of the most prevalent and fatal forms of disease; and, as a consequence, can apply means of prevention or treatment in a much more direct and definite way than was formerly the case. For example, a hundred years ago nothing was known of the difference between typhus and typhoid fevers. We have now discovered that the first is a disease propagated largely by aerial contagion and induced or aggravated by over-crowding, the preventive means being isolation, light and fresh air; while the second is due to a minute vegetable organism, a bacillus, and is propagated mainly by contaminated water, milk, food and clothing; and that the treatment of the two diseases should be very different.

The most important improvements in practical medicine made in the United States, have been chiefly in surgery in its various branches. We have led the way in the ligation of some of the larger arteries, in the removal of abdominal tumors, in the treatment of diseases and injuries peculiar to women, in the treatment of spinal affections and of deformities of various kinds. Above all, we were the first to show the uses of anesthetics—the most important advance in medicine made during the century. In our late war we taught Europe how to build, organize and manage military hospitals; and we formed the best museum in existence illustrating modern military medicine and surgery. Our contributions to medical literature have been many and valuable; and our government possesses the largest and best working medical library in

the world. We have more doctors and more medical schools, in proportion to the population, than any other country, and while this is not good evidence of progress, I am glad to be able to say that the standard of acquirements in medical education has been, and is now rising, and our leading medical schools are now being equipped with buildings, with apparatus, with laboratories, and most important of all, with brains, which enable them to give means of practical instruction equal to any to be found elsewhere.

As regards preventive public medicine and sanitation, we have not made so many valuable contributions to the world's stock of knowledge,—chiefly because until quite recently, we have not had the stimulus to persistent effort which comes from density of population and its complicated relations to sewage disposal and water supplies; nor have we had the information relative to localized causes of disease and death which is the essential foundation of public hygiene, and which can only be obtained by a proper system of vital statistics. We can, however, show enough and to spare of inventions in the way of sanitary appliances, fixtures and systems for house drainage, sewerage, etc.; for the ingenuity of inventors has kept pace with the increasing demands for protection from the effects of the decomposition of waste matters, as increase of knowledge has made these known to us. The total number of patents granted for sanitary appliances during the last decade (1880–1890) is about 1,175. If good fixtures necessarily involved good plumbing work, we could easily make our houses safe so far as drainage is concerned; but a leaky joint or a tilted trap makes the best appliance worthless. The impulse to improvements in this direction has come mainly from England, where most of the principles of good work of this kind have been developed; but we have devised some details better adapted to our climate and modes of construction, and while many of the patent traps and sewer-gas excluders are only useful in the patent-law sense, and some not even in that, it is nevertheless true that the safety, accessibility and good appearance of plumber's work has been largely increased during the last few years by patented inventions. Much the same may be said with regard to heating appliances, including ventilating stoves and fireplaces, radiators, etc., but I am unable to express any enthusiasm with regard to what are commonly called patent ventilators.

No doubt the greatest progress in medical science during the next few years will be in the direction of prevention, and to this end mechanical and chemical invention and discovery must go hand in hand with increase in biological and medical knowledge. Neither can afford to neglect or despise the other, and both are working for the common good. If the American patent system has not given rise to any specially valuable inventions in practical medicine or in theology, it must be due to the nature of the subjects, and not to any fault of the system.

IN Komarui, a village near Great Kanisza, a mob of peasants, thinking that a whole family had been fatally poisoned by a prescription of antipyrin and calomel prepared for a sick child, were about to murder the two physicians of the place, but were pacified by the offer of one of them to swallow the rest of the medicine, which he did on the spot. It was discovered later that the family had died of carbonic oxide poisoning.

## Original Articles.

TWO CASES OF SPINA-BIFIDA.<sup>1</sup>

BY E. H. BRADFORD, M.D.

THERE are certain surgical affections which still await farther investigation before they may be considered as definitely amenable to operative treatment. Among them may be mentioned spina-bifida; and the object of the present paper is to call attention to the need of more thorough examination, and a record of all cases, successful as well as unsuccessful.

Two cases will be presented, which resulted fatally, where it is possible that a better method of procedure might have given better results.

CASE I. A fairly nourished infant, five months old, with a fluctuating, translucent tumor projecting from the lower cervical region, in the median line. The tumor presented all the characteristics of spina-bifida, did not increase when the child cried, and did not diminish on pressure, and the inference was that the communication with the spinal cord was not large.

The walls were thin, and there was some ulceration in the skin; the pedicle was relatively small, and ligation seemed feasible. A silver wire was passed subcutaneously around the pedicle without opening the sac, making a wire purse-string suture between the sac and the skin. On tightening the wire, the pedicle was compressed. The sac was then cut off, a few stitches taken to unite the serous surfaces, and the wound dressed with aseptic gauze. There was

little or no leakage at first, but in twenty-four hours a slight discharge of serous fluid was noticed, which increased, and later became copious, saturating all dressings. The patient was quiet after the operation, but became restless at the end of twenty-four hours, and convulsions occurred on the fourth day, followed by death.

CASE II. The second case has a double interest, in the matter of diagnosis, and also as a surgical warning. It is of a child four years of age, with a swelling in the right buttock, somewhat to the right of the median line. The tumor was apparently movable to a slight degree, but seemed to be attached firmly to the sacrum. There was no pain. The tumor was not prominent, but on being grasped it seemed to be at the right of the median line, giving the sensation on palpation of a fatty tumor. The child was in perfect health, and walked about, though there was paralysis in some of the muscles of the right leg. The tumor had existed since birth, and had not been painful except for a short time. A diagnosis was made of a sacral tumor of unknown nature, — probably fibroma, — not connected with the spinal cord or the canal. This opinion was partly based on the surgical dictum, mentioned by some authorities, that spina-bifida is always in the median line. A three-inch incision was made through the skin, and revealed a large amount of fatty tissue.

An aspirating needle was introduced, and no fluid discovered. No distinct fatty tumor was found, though an unusual amount of fatty tissue was present. At the bottom of this fatty tissue a firm, fibrous mass was found, which grated on the knife. This was incised, and a large amount of clear, serous fluid issued. On inserting the finger, an opening between the sacrum and the last lumbar vertebra was found, large enough to admit the finger directly into the spinal canal. The incision was closed by a double layer of sutures, and a firm pressure made upon the wound by means of aseptic pads. There was some shock after the operation, but the subsequent course was similar to the previous case, except that the amount of serous discharge was more copious. Death occurred at the fourth day, preceded by convulsions.

In reviewing these two cases critically, it may be said that in the first there was a mistake in method or technique. Some operative interference was manifestly indicated by the situation and size of the tumor, and furthermore the size of the pedicle would appear to have justified such measure. Probably silver wire was not so suitable for ligation as silk would have been, the latter being more pliable, and a Staffordshire knot would have answered better than any other in giving complete apposition of the serous surfaces. This would have involved puncturing of the sac, which the subcutaneous purse-string suture avoided, but the escape of the fluid would have been slight if the ligation were properly applied. The purse string, which was used, could not be drawn tightly enough in delicate tissue. Instead of ligation Mr. Mayo Robinson's method, to be mentioned later, would perhaps have been more advisable, as it would probably have given less danger of injury to the elements of the spinal-cord, if any existed in the tumor, or it is possible that the injection of Morton's fluid would have been advisable in this case. At any rate, it could have been tried before other operative interference. The reason why it was not tried was, it was thought, that, owing to the position of the tumor in the lower portion of the cervical region, great danger would be run of the irritating effect of iodine upon the upper part of the spinal cord, and as the child appeared a healthy one, operation was preferred.

In the second case the error in diagnosis is instructive. It was largely based upon the position of the tumor, which was to the right of, not on the median line, as is mentioned by some surgical writers to be invariably the case in spina-bifida (Treves and Holmes). The central position of spina-bifida, is, however, by no means universal; in addition to the case here reported, the writer would mention another presenting a large tumor undoubtedly of the nature of spina-bifida in the sacro-lumbar region, situated on the left side, reaching from the median line to the angle of the ribs. The tumor in the case here reported was also more diffused, less prominent, and situated more deeply than is ordinarily the case in spina-bifida. The aspirating needle discovered no fluid, probably because it was introduced without due care to keep the canal clear as the needle passed through a thick, fibrous sac. The injection of Morton's fluid in this case also should have preceded any operative interference, though there would have been some difficulty, owing to the depth of the sac and the amount of overlying fatty tissues, to have injected the fluid satisfactorily. Possibly the method of direct incision, with subsequent packing the sac with iodo-

<sup>1</sup> Read at the Meeting of the Surgical Section of the Suffolk District Medical Society, January 7, 1891.

form gauze, would have been better than the one adopted, that is, sewing the divided tissues together, for, at the depth at which the firm fibrous tissues lay, tight suturing was difficult.

In both of these instances it would appear that the constant drain of the cerebro-spinal fluid after operation was largely influential in death; and this should be guarded against, and prevented, if possible, in all operative interference upon these tumors.

In attempting to form an estimate of the relative value of the different methods of operation at present, it is probable that great reliance cannot be placed upon statistics. Cases of spina-bifida which are operated upon are not numerous, and have not, as a rule, been grouped together in large numbers under the observation of any one surgeon. Isolated cases give but little value to statistics, if successful cases are reported more freely than unsuccessful ones, as is too frequently the case.

The careful investigations by the London Clinical Society give our most reliable statistics, but it would appear probable from the figures given that it has been found impossible to collect a complete list of unsuccessful cases, while successful cases are readily found. The largest number of cases which has been reported by any one surgeon are those of Mr. Morton, of Glasgow, and are therefore of value.

In the London Clinical Society Report (1885) of 71 cases injected by Morton's solution (iodine gr. x, iodide of potash gr. xxx, glycerine  $\frac{1}{2}$  j), 35 recovered, 27 died (7 from meningitis, 2 with convulsions, 5 from shock), 5 were unrelieved, 4 relieved. These cases were collected from published cases, and were not all from the record of one observer. The mortality is 37 per cent.

In Mr. Morton's collection of 65 cases, published in his book (1887), 55 recovered, 10 died, a mortality of 15 per cent. These cases were not, however, all observed by Mr. Morton; and his own personal statistics are as follows: 29 cases, 6 deaths, a mortality of 20 per cent.

In addition to these reported cases, the following have been published more recently:

Bishop,<sup>2</sup> two cases, with one recovery and one death, the tumor being in the lumbar region; Tennant,<sup>8</sup> Cawn, Voight,<sup>4</sup> and Morton<sup>5</sup> each report successful cases; Abbe,<sup>6</sup> one death; making five recoveries and two deaths; that is, 40 per cent mortality.

To what extent these figures represent the actual mortality from the procedure, it is impossible to state positively; but it is probable that the figures present the most favorable results, as many isolated unsuccessful cases are undoubtedly unreported while successful cases are not often unrecorded but it is probable that the figures present the most favorable results which can as yet be drawn from statistics.

It is irrational to suppose that in cases where there is a large opening into the canal the injection of iodine, even if guarded by manual care, would be of assistance; and it is for this reason that the method cannot be used indiscriminately. The presence of hydrocephalus, or the rapid disappearance of the tumor on pressure, a thin-walled ulcerated sac, and a feeble condition of the child may be regarded as contra-indications to

the injection of iodine. It may be presumed that the cases where the method is successfully used is where the opening is small, where the connection between the tumor and the cord is not very free; in other words, it is in such cases as it might be used in a condition analogous to congenital hydrocele.

It is not to be supposed that the injection of simple iodine, iodoform, or Lugol's solution has any especial advantage over the injection of Morton's solution. An additional successful case where iodine was injected; and another,<sup>7</sup> where Lugol's solution, has been recently mentioned. Fisher<sup>9</sup> reports an unsuccessful case of injection of iodoform. The London Clinical Society (vol. xviii) reports 26 cases of the injection of iodine, — five deaths, a mortality of 18 per cent.

It should be borne in mind that in a number of instances a spontaneous cure has taken place in the spina-bifida. This has occurred usually by a rupture of the sac, with a discharge of the fluid contents, and thickening and shrinking of the tumor. In these instances it is fair to suppose that the connection between the spinal canal and the tumor has become small, and has become obliterated. Instances of this sort would, perhaps, have been cured more rapidly by the injection of some irritant, if this had been used at the proper time. These cases of spontaneous cure must be rare.

In the report of the London Clinical Society, of 61 cases not treated, 25 died, 14 recovered, 21 were not accounted for. Deming<sup>9</sup> states that in 57 cases observed by him, of 32 for whom there was no operation, at the end of two years, none were alive.

Of 32 cases observed in the St. Petersburg Foundling Home, 30 ended in death in the course of a new first months of life, and only two survived a year (Zenkenko).

Butler Smythe<sup>10</sup> mentions three cases, complicated with hydrocephalus, with two deaths from rupture of the sac in seven and five weeks, and a third death from convulsions, without rupture of the sac. To these the writer would add three cases reported: one by De. Forrest,<sup>11</sup> with death; one by Dr. Sutton,<sup>12</sup> with death; one by Dr. Clutton,<sup>13</sup> with recovery. Also two cases; one in a child of eleven, where spontaneous disappearance of the tumor appeared to have taken place, judging from the assertions of the parents and the evidence of a patent and bifurcated spinal column in the lumbar region; and in a second case (lumbar region) where at the age of two, spontaneous rupture occurred with recovery. The child gave every evidence of health, though a sinus, which occasionally discharged, remained over the shrivelled tumor. The child's legs were not as strong as normal, but the child was able to run about freely.

Summing all the above cases, we have 112 cases; 94 deaths; 19 recoveries; a mortality of over 80 per cent. This, however, probably must understate the actual mortality, as many cases of death are not published.

Of the method of more radical operative interference, the statistics are exceedingly meagre. The London Clinical Society has collected 46 cases of puncture (that is without injection), with 30 deaths, or a mortality of 67 per cent.; of excision 23 cases, with

16 recoveries and 7 deaths, or a mortality of 30 per cent.; of ligature 16 cases, with 6 deaths, or 37 per cent. mortality. In some of the cases the operation was performed before the days of antiseptic surgery, and necessarily may be supposed to give less favorable results than can be obtained now.

Later than the date of publication of the Society's Report, Mr. Mayo Robson<sup>14</sup> presented to the London Clinical Society the records of four successful cases of operative treatment (March 27, 1885). In addition to these the following cases (11, with three deaths) have been collected since the publication of the Clinical Society's Report:

Reporter.	Age.	Situation.	Operation.	Result.
Hard. Therapeutic Gazette, 1889, v, 660 . . . . .	16 months	L. S.	Aspiration { Excision	Recovery
Barton. Lancet, 1886, ii, 626 . . . . .	3 weeks	L.	Incision	Death

Willard. University Medical Magazine, May, 1889. . . . .	....	....	Excision	Death
Borelius . . . . .	10 months	L. S.	Excision	Death
Bondieu. Hygiea, Stockholm, September, 18-9 . . . . .	....	....	Excision	Recovery
Dollinger. Edinburgh Medical Journal, 1887 . . . . .	5 years	....	Excision	Recovery
Groner. Americau Lancet, 1888, xlii, 284 . . . . .	3 months	C.	Excision	Recovery
Evans. New York Medical Journal, 1888, xlviii, 205 . . . . .	6 years	L.	Excision	Recovery
Howson. Lancet, July, 1884, 177. . . . .	14 days	L.	Excision	Recovery

Adding to these Mr. Robson's four successful cases and the two cases reported in this paper, we have 17 cases in addition to those collected by the London Clinical Society. Those collected by the London Clinical Society contain some cases treated before the introduction of aseptic surgery. Those reported in the tables here were probably all treated under aseptic precautions. Of these 17 cases there were five deaths, giving a mortality of 29 per cent.

It would not be difficult to over-estimate the value of the above statistics; in fact, it can be said that they can have nothing except a proximate value. But, such as they are, we may conclude that the mortality of the affection, if untreated, is, at least, 80 per cent. (112 cases with 91 deaths). The mortality from the injection of Morton's fluid of all reported cases (143 cases and 39 deaths) is 27 per cent. The mortality of all cases operated upon by radical measures and published is (56 cases and 18 deaths) 32 per cent.; or, taking the pre-umably aseptic cases (17 cases and five deaths), a mortality of 29 per cent.

Much needs to be learned in regard to the technique of operative interference, where operative interference is decided upon. The amount of danger from the loss of fluid during the operation is probably not very great, but there is great danger from the constant leaking of cerebro-spinal fluid after operation. Every attempt, therefore, should be made to promote a speedy union of the serous surfaces, and to prevent any subsequent leaking. Attention has been called to this fact by Mr. Robson, of Leeds, who advises the bringing together of the serous surfaces of the meninges as in peritoneal surgery. Lines of suture of the skin and of the meninges should not come opposite each other.

Mr. Mayo Robson also advises the retention of as much of the covering of the sac as is possible; and this would accord with the experience in one of the cases here reported, where the fibrous tissue covering the sac was extremely firm. He also calls attention to the advantage, where the integument is thin, and opening of the spinal canal large, of turning a flap of skin over the tumor by a plastic operation. And if the spinal cord or nerves are found blended with the sac, — and this cannot often be told until dissection of the skin from the meninges is made, — he advises excisions of portions of the redundant sac at places between the nerves, replacing the nervous structure into

the canal, and covering the canal with skin, with free drainage between the skin and meninges.

Where this is not possible, the membranes can be punctured, the collapsed sac placed into the canal, and the adjacent skin brought over to cover the whole mass. The collapsed sac is used, if the bony ring is small, much in the same way as is the sac in McEwen's method in the radical operation for inguinal hernia.

In conclusion, it should be admitted that the operative treatment of spina-bifida is as yet in an experimental stage; but it is also true that conservative treatment is apparently most unsatisfactory. Manifestly where the tumor is extensive, with a fissure involving a large portion of the vertebral canal, and where complete paraplegia is present, no operative treatment can be undertaken. If the communication of the sac with the canal is comparatively narrow, operative interference would appear to be justifiable, the condition of the patient permitting.

## RHEUMATIC FLAT-FOOT<sup>1</sup>

BY F. B. HARRINGTON, M.D.

SINCE the appearance of the very valuable paper by Dr. Royal Whitman on flat-foot,<sup>2</sup> which was published two years ago, I have studied the subject at the Out-Patient Department of the Massachusetts General Hospital with a great deal of interest. I have found that whatever disables the motion or the power of the foot, be it disease or injury, may be followed by tem-

<sup>1</sup> Read at the Meeting of the Surgical Section of the Suffolk District Medical Society, January 7, 1891.

<sup>2</sup> Observations on Forty-Five Cases of Flat-Foot, with particular reference to Etiology and Treatment. Royal Whitman, M.D. Boston Medical and Surgical Journal, June 11 and 21, 1888.

porary or permanent flattening, or other deformity of the feet, or by those symptoms which, although no deformity exists, may be attributed to analogous conditions.

The amount of deformity depends upon the amount of displacement of the bones, and the amount of yielding of tissues. The amount of pain is not at all dependent on the amount of deformity. The history of nearly all old cases of flat-foot is that they have been treated for months or perhaps for years, for rheumatism, with little or no relief. Very few of the cases are in any way connected with rheumatism except that, being disabled joints they are more liable to subacute rheumatic arthritis like other crippled joints. There is, however, a class of cases in which the primary cause of the flat-foot and the accompanying disability, is rheumatism. These two patients illustrate this fact.

J. G., aged thirty, is a car conductor, of previous good health. Eighteen months ago he had an attack of inflammatory rheumatism. Nearly all the joints were swollen. He was ill for six months. He then began to go about. The feet began to show deformity, and to give him great pain. There had previously been no flattening of the feet. When I first saw him the feet were greatly deformed. They were swollen, rigid and flattened. The extensor muscles of the toes were in a state of spasm. The reflexes of the feet and legs were increased. There was no motion at the ankle, nor lateral motion in the tarsus. There was atrophy of the calf muscles, the leg measuring but ten inches in circumference. The disability was increasing rapidly. Under ether the displacement of the tarsal and metatarsal bones was corrected; and foot-plates were made. The mobility and usefulness of the feet have increased, and although there is still much to be done before the patient will be able to resume his work, the outlook is favorable.

The second patient is a shoemaker, age thirty-five. Fourteen years ago he had an attack of articular rheumatism, which he says "settled in his feet." It finally disappeared and he recovered full use of his feet. Seven years ago he had another attack, and since that time the feet have become more and more deformed, until a very marked degree of deformity has resulted, with much disability. He was unable to work continuously. The feet were rigid, and the extensors of the toes were in a state of spasm. The muscles of the calf were atrophied and the reflexes were increased. The deformity in this case could be corrected by gradual pressure without ether. This was done, and the feet were kept in side splints for two weeks, in a corrected position. Plates were then made, and the patient was instructed about proper shoes and walking. The relief to him had been very great. He can use his feet with comfort.

These two cases illustrate the production of marked flat-foot after rheumatism. There is a considerable number of cases in which, after rheumatism, the deformity is slight or wanting, but the disability is great. Sometime this disability is due merely to the arthritis which persists after the disappearance of the disease. Often it is a combination of arthritis and those conditions, which, for the want of a better general term we call flat-foot. Great relief can be afforded in many of these cases, by supporting the arch of the foot, and I believe there is no better way of doing this than by Whitman's plates.

The reasons for the appearance of flat-foot after rheumatism are many. The muscular power of the leg and foot is diminished. The tissues are softened by inflammation. The effort to use the foot with the least discomfort, that is, with the least motion, induces the patient to abduct the feet. The patient swings the feet along with the toes diverging and walks with little or no motion at the ankle. This necessarily throws him upon the inner border of the foot, and on account of the weakened state of the foot, is more likely to produce breaking down of the arch. At the same time, the abductor muscles, by their persistent effort to evert and fix the foot, are brought into a state of spasm and become contracted.

Whitman<sup>8</sup> has recently shown that many cases of what is called chronic sprain of the ankle are in reality cases of "persistent abduction" of the foot, which are never relieved until the deformity is corrected, and the foot strengthened and kept in its corrected position.

The point to which I especially wish to draw attention, is the importance of correct use of the feet after rheumatic attacks; and the avoidance of such deformity as we have seen in the two cases presented. If patients use the feet while they are still painful, they should be watched to see that they do not do positive injury to them. If disability persists, even though no deformity can be seen, much relief may often be obtained by the use of the foot-plates. The use of the plates should be combined with massage, and appropriate medical treatment as indicated by the case.

## HYPNOTISM.

BY HAROLD WILLIAMS, M.D.

At a meeting of the Boston Society for Medical Improvement held on January 26th, a paper on hypnotism was read by Dr. Hamilton Osgood, and subsequently discussed by members of the Society. Dr. Osgood's views on this subject are so well-known to me that their reiteration on this occasion did not surprise me. But I confess that I was surprised in reading the discussion of that paper to find that no one there present considered the subject of sufficient importance to cause him to raise his voice in protest against what I believe to be a wholly unjustifiable and distinctly dangerous therapeutic measure. If Dr. Osgood or men of his high character and attainments, were the only exponents or disciples of the French school in the Massachusetts Medical Society or in the State of Massachusetts, I should not regard it as my duty to challenge his statements nor his hypnotism; but unfortunately they are not. Other and less scrupulous followers of the French school are springing up among us and several painful instances of the abuse of this dangerous agent have come to my knowledge, which compel me to protest against the rapidly increasing employment of hypnotism.

The benefits to be derived from hypnotism, according to Dr. Osgood, are from what is called hypnotic suggestion; and the process may be briefly described as follows: The patient is hypnotized, and during the hypnotic sleep she is told that on awakening her symptoms will disappear. (I say *she*, because the subject is

<sup>8</sup> The Treatment of Persistent Abduction of the Foot, commonly known as Chronic Sprain of the Ankle. New York Medical Journal, October 11, 1890.

generally a woman.) She is then awakened, and her symptoms have disappeared, to a greater or less extent, and for a longer or shorter time. On the reappearance of her symptoms she is again hypnotized, and again relieved, and in many instances repair takes place during the immunity from symptoms. It is applicable, according to Dr. Osgood, to pain of every sort, from the dull torment of the aching tooth to the agony of labor. It cures drunkenness, stuttering, the cocaine habit, hay-fever, irregular action of the heart and the pain of rheumatic gout; though, to quote Dr. Osgood's naïve words, "Hypnotic suggestion did but little permanently for the painful and deformed joints." This is substantially what Dr. Osgood claims for hypnotism, or, in other words, he claims that it is applicable to every form of subjective symptom, to all functional diseases, and to the *symptoms* of organic disease. It is not claimed that by hypnotism we can accomplish anything that can be accomplished in no other way. On the contrary, hypnotism is only claimed by its advocates to accomplish what ether, chloral, the bromides, sulphonal, phenacetine, valerian, electricity, etc., will accomplish also. It is claimed to possess advantages, as a therapeutic measure, which are shared by a large class of drugs. These are, in brief, the advantages of hypnotism. Its disadvantages may be summarized as follows:

(1) It is dangerous to the health of the patient, both in its immediate and remote effects.

(2) It is dangerous to the community, and is liable to the greatest and most flagrant abuse.

(3) It is dangerous to the physician and through him to the whole medical profession.

Now, to substantiate these assertions, which I believe to be a fair statement of the objections to hypnotism, let me first say that an hypnotic *séance* is not always the harmless procedure which Dr. Osgood describes. Only last week a case was reported by Dr. Julius Solow in the *New York Medical Journal*, in which convulsions, aphasia and catalepsy, lasting for ten days or more, followed upon "an experiment with hypnotism." And its remote effects upon the patient are still more to be feared. In the first place it weakens the self-control of the patient, as is shown by the ease with which she is re-hypnotized. Every time that she is hypnotized facilitates the repetition of the process. She has lost her power of resistance against hypnotism. I have even known of cases in which by frequent repetition the patient could be hypnotized by the operator in an adjoining room.

What really occurs at the hypnotic *séance* is this: The operator tells his patient he is going to make her sleep. He looks at her fixedly; frowns at her or smiles at her confidently, with a smile which one patient describes as making her feel cold all over. He tells her she will soon be "as wax in his hands"; that she will soon become sleepy, but that she must not resist that drowsiness, for it is that which will enable him to cure her. Then he sits down before her, and requires her to look at some bright object; sometimes to look into his eyes. In this latter case he looks at the bridge of her nose; and he, by looking at one object, can sustain his gaze longer than she can while looking at two. Or he tells her to look into his eyes, and then comes very near to her, thus bringing a great strain upon the muscles of the eyeball. This is a favorite method, and at the operator happens to be myopic, as I have noticed to be the case with the most success-

ful hypnotizers I have seen operate, he can sustain his gaze for a long time without strain, while the contrary is true of the patient with normal vision. This latter procedure, it will be seen, is closely analogous to a popular method of overcoming sleeplessness, namely, that of shutting the eyes and turning them inward.

When the patient begins to become conscious that her gaze is weakening while that of the operator remains the same she thinks he is stronger than she is; she begins to lose her equipoise and becomes terrified; then the physician makes mysterious passes with his hands, or strokes her eyelids or her forehead. Sometimes he makes a blowing sound. Then he tells her that she is sleepy; that she is almost hypnotized; that she is hypnotized and by this time in most cases she is hypnotized. Now what has probably happened in this case is, that the operator has led her to distrust her own power of self-control. He has made her believe that she is going to sleep and by expectant attention she has gone to sleep. In other words she has hypnotized herself at the suggestion of another. But if we could look into her mind we should find that by a feeling of distrust of her power of control; or by fear of the power of the operator; or by terror, she has been hypnotized by exactly the same process employed by the rattle-snake.

If this is not the method as it is applied by Dr. Osgood I am very glad indeed to hear it; but it is the method used by others whom I have seen practising hypnotism. Now, that power in virtue of which a person becomes hypnotized is a power inherent in the persons themselves. They could, in many instances, probably hypnotize themselves without the assistance of another if they only thought so. But they do not think so. They believe that the operator has an occult power over them; that he *magnetizes* them; that he *wills* them. They believe that he is stronger than they are and that if he commands they must obey. They yield up their wills to him and I maintain that any one who yields up his will to another has weakened his mind by that submission. For the time he has lost the check of personal responsibility. The best subjects for hypnotism are hysterical, emotional, ill-controlled, women, and I do not see how such persons can be lead to believe in and speculate about the mysterious and the occult without being permanently injured thereby. And believing that they are "mesmerized" or "willed" or influenced by the operator near at hand, the step is not a long one to believing that they can be "willed" or "mesmerized" or influenced by the operator at a distance. An instance of this belief recently came to my knowledge when I saw an emotional woman spring to her feet, rapidly pace the room, wildly gesticulating with her arms, laboring under the delusion that she was being treated by an operator at a distance. She declared that her legs were numb; that her arms were paralyzed. She believed in the so-called telepathy and was nearly beside herself at the time. Such a condition as she was in is not far removed from the borderland of emotional insanity and yet it is a condition of mind liable to be produced at any time in the subjects of the hypnotic experiment.

As I have said before, the power of becoming hypnotized is a power inherent in the patient herself. Any person who is led to believe that it is a power in the will of another is deceived, and the mind of such a person must be weakened by the acceptance of a false belief.

In substantiation of my second assertion, that hypnotism is subversive of good morals and liable to the greatest and most dangerous abuse, it seems to me little need be said. A woman who can be induced by hypnotism to perform the peculiar and unusual acts which have become familiar to us from the columns of the medical journals, can also be induced to perform other and more hurtful acts. All that is requisite is the *animus* of the operator; and it does not require a wide knowledge of human character to know that this *animus* will be forthcoming. Three instances of the asserted abuse of hypnotism have come to my knowledge, though the evidence in these cases is, as it of course always must be, incomplete and untrustworthy. In one of these cases, the subject, a woman, assured me as her physician, that her husband had hypnotized her and through the influence of suggestion had coerced her into the performance of an act that was repugnant to her, and which I need not describe here. Of course, such an assertion as this is valueless, because the woman had no means of knowing what her husband had suggested while she was in the hypnotic state, and the husband if questioned would probably deny that he had so influenced his wife. Yet he admits that he frequently practises hypnotism upon her, and upon other persons as well. I cite this case as showing the difficulty of substantiating charges of this nature, a difficulty which contains a two-fold menace since it enables crimes to be perpetrated with impunity, and since it opens the door to the blackmailer and the slanderer. And I can also say in this connection that the wife's mind has evidently deteriorated since her husband has practised hypnotism upon her, and that when I remonstrated with him and pointed out what I believed to be the inevitable result of his experiments, he replied that "other Boston doctors practised hypnotism and declared it to be harmless." The other instances are accusations of a similar nature. The employment of hypnotism as a therapeutic measure is also dangerous to public morals, because, if sanctioned by regular physicians, it will be employed by charlatans and others, for mercenary and immoral purposes. They will use it more openly, and when it becomes better understood, more generally; and the fact that it is considered a legitimate agent by reputable physicians will be a defence for its employment by the disreputable. Whereas if it is discountenanced by the regular profession, who are well known to have the welfare of the public at heart, it will be practised less openly by charlatans, and those who employ it will be looked upon with suspicion.

It is dangerous to the physician who employs it, and through him to the good standing of the whole medical profession, because its nature is fraud, because its success depends upon charlatanism and deceit, and because, in most instances, to practice it successfully one must deceive his patient, and delude her into the belief that he has "the power over her," that he can "influence her" or "will her"; whereas, as I have shown before, he simply induces her to influence herself. The more mysterious he is, the more impressive his signs and frowns, the better actor he is, the more successful hypnotizer he is—in other words, the greater charlatan he has become. And I do not see how the employment of a fraudulent means can fail to lower the moral tone of the physician who employs it. He will become more and more accustomed to depend upon the influence of the imagination of his patients;

more and more he will practise upon their credulity; and more and more will he become a charlatan, a humbug, a *poseur*. Let us recognize the force of the imagination by all means; let us employ it if we must; but let us remember that the one thing which most widely separates the regular practice of medicine from the practice of the charlatan is truthfulness and honesty; and I say, let us preserve our truthfulness, even at the expense of hypnotic experiments.

And a second source of danger to the physician is that by employing hypnotism he lays himself open to all sorts of charges by patients and their friends that he makes unworthy use of hypnotic suggestion. Several instances where such insinuations have been circulated against physicians employing hypnotism have come to my ears.

To recapitulate, therefore, we find that in hypnotism we have a therapeutic agent which is injurious to the physician employing it; to the profession which sanctions it; to the patient upon whom it is practised and to the community which tolerates it. And we find, on the other hand, that it accomplishes nothing which other, both safer and better understood therapeutic agents, will not also accomplish. In other words, we find no reason why we should adopt hypnotism as a therapeutic agent and every reason why we should not.

## RECENT PROGRESS IN SURGERY.

BY H. L. BURRELL, M.D. AND H. W. CUSHING, M.D.

### THE ETIOLOGY OF ACUTE SUPPURATION.<sup>1</sup>

AN interesting review of Stienhaus's exhaustive work on this subject closes with the following paragraph which is of surgical interest:

"That so far as our present knowledge is to be relied upon, we are justified in believing that suppuration in the living tissues is the result of some certain chemical action, which may be combined with the presence of bacteria, or may be obtained from pure chemical substances without the presence of micro-organisms."

Whether this is merely of theoretical interest or not; and that practically in clinical work all suppuration is due to microbes is still a question unanswered. It is of especial interest in regard to cold abscesses, whose pathology is still unsettled. Steinhäus also claims to have demonstrated that the action of the same micro-organisms varies greatly in different animals, thus explaining many apparently contradictory experimental results.

### CARDIAC IMPULSE IN RELATION TO OPENING THE CRANIUM, THE PLEURA AND THE CAVITY OF THE ABDOMEN.<sup>2</sup>

Tausini, Modena, has investigated this subject by experimentation on rabbits, and from twenty-five observations has formulated the following conclusions:

The trephine, in opening the skull, has much less influence on the heart's action than the chisel. In order to reduce the effect of the chisel to a minimum a very small instrument must be used and held at an inclination of thirty degrees at least, to the surface of the skull. When the skull has been previously in-

<sup>1</sup> W. W. Van Arsdale. *Annals of Surgery*, 1890, vol. xii, 16.

<sup>2</sup> G. R. Fowler. *Annals of Surgery*, 1890, vol. xii, 253.

jured and opened, the chisel has less effect on the heart's action.

Extra dural tamponing exercises a much more disadvantageous effect on the heart's action than does direct pressure on the brain substance. A venous hemorrhage can always be controlled by the latter without severe disturbance of the heart.

Irrigation of the ventricles, when a free outlet for the return fluid existed, had no effect on the heart.

After ten thoracic observations he found that open pneumothorax, right or left, affected decidedly the cardiac action primarily by disturbance of rhythm; later by diminution of cardiac movement.

Continuous irrigation of the pleural cavity with cold ( $11^{\circ}\text{C}$ ) or warm ( $38^{\circ}\text{C}$ ) water retarded decidedly the heart's action and accelerated death.

The action of non-toxic antiseptics was negative.

In the abdomen in sixteen experiments it was found that continuous persistent irritation of the nerves of the abdominal cavity, in either a normal or hyperæmic peritoneum, either by exposure of intestinal coils to atmospheric air for different lengths of time or to different temperatures (wet clothes or sponges or irrigation fluids), could retard or arrest cardiac action.

#### IODOFORM INJECTION OF COLD ABSCESSSES.

This method, first published by Verneuil, has attracted considerable attention, and many favorable accounts have, from time to time, been reported. It was claimed to have been free from danger. L. Barrois's<sup>8</sup> experience with this method (puncture and subsequent injection of an iodoform-ether solution) in this respect is especially interesting. His results were, as a rule, very satisfactory, but in one case disastrous. A large cold abscess in the left thoracic region in an otherwise healthy soldier, age twenty-four, was injected with fifty to sixty grammes of a 5 per cent. solution. Immediately after the injection, symptoms of severe collapse appeared, and death resulted on the tenth day. The result was not perhaps a case of pure iodoform intoxication, as Barrois considers. Possibly a communication of the abscess cavity with the thoracic cavity may have caused the collapse.

#### HETEROPLASTIC OPERATION FOR CLOSING TREPHINE DEFECTS IN THE SKULL.

A. Frenkel, Vienna, claims to have demonstrated by experimentation on dogs, that celluloid plates can be used to close defects in the skull resulting from trephining. The plates are placed in position, and the pericranium and skin united by sutures over them. Primary union shuts in the plate, thus closing the skull in a manner capable of resistance. The plates remain in position unchanged.<sup>9</sup> Of interest in this connection is König's case,<sup>10</sup> in which he closed an oval-shaped defect in the parietal region (8 cm. by 5 cm.) by a plastic operation. He implanted a flap (pedicle attached) of skin, periosteum and a thin layer of bone similar to the method described by Rötter.

#### IRRIGATION OF THE LATERAL SINUS FOR SEPTIC THROMBOSIS CONSEQUENT TO AURAL DISEASE.

Mr. Ballance has written an important article<sup>11</sup> on this subject in which he describes a method he has satisfactorily employed in the treatment of several

very severe cases. It consists of division of the internal jugular vein after ligation below the thrombus and then irrigating the portion of the vessel between the divided end and the trephine opening in the lateral sinus through the mastoid. The details of this procedure are described in the article above referred to. Mr. Ballance emphasizes the difficulty of making an early diagnosis, especially when there is no history of a preceding otorrhœa, and insists upon the futility of operative treatment which did not include ligation of the internal jugular vein.

The principal diagnostic points to be relied on are: History of an otorrhœa; sudden onset of the disease; extreme and rapid oscillation of temperature; repetition of rigors and vomiting; optic neuritis and other cerebral symptoms; tenderness and swelling in the mastoid region, with stiffness of the neck.

#### SURGERY OF THE LATERAL VENTRICLES OF THE BRAIN.

Keen<sup>7</sup> reports three cases of operation for the relief of effusion into the lateral ventricles and two cases are communicated by Mayo Robson. The operation is in a tentative state, but Keen draws the following conclusions:

(1) Injuries involving the ventricles, the result of compound fracture, or of trephining, and involving greater disturbance of the cerebral substance, are not necessarily fatal, for ten of the twenty-six cases here reported have recovered. In these few cases compound fractures and extensive injuries, unless primary fatal, seem to be less dangerous than rupture of the ventricle from simple fracture. They should be treated antiseptically, in precisely the same manner as wounds in other parts of the body, by the establishment of asepsis, drainage, and the usual later treatment. If pus follows, or the cerebro-spinal fluid becomes dammed up, causing symptoms of pressure, incision and free drainage should be resorted to.

(2) In cases of simple fracture involving the ventricles, experience would seem to indicate that it would be wise not to attempt any operative procedure unless threatening symptoms supervene. If necessary, I should recommend that the cyst containing cerebro-spinal fluid should be continuously and slowly drained by a small bundle of horse-hairs, rather than by free evacuation. But, I believe, in the majority of cases, constant pressure, and but little active treatment, would meet such symptoms as might arise. Possibly slight pressure would be all the treatment that would be necessary.

(3) Abscess of the brain bursting into the lateral ventricle has been thus far uniformly fatal, and demands the promptest treatment possible. The suggestion made for instant bilateral trephining and irrigation of the ventricles, can at least do no harm, although the possibility of its doing any good is but slight in so fatal a condition.

(4) Hydrocephalus, whether acute or chronic, is usually a fatal disease.

(5) Surgical procedures for tapping the ventricles for its relief are easy, and certainly do not *per se* involve great danger.

(6) Whether they will cure the disease is as yet not determined. In acute effusions tapping, with or without drainage, as may be thought best, will certainly save some lives otherwise doomed to be lost; and in

<sup>7</sup> *Ann. N. Y. Acad. Med. Sci.*, 1890, xvi, 3.

<sup>8</sup> *Wien. klin. Wochenschr.*, 1890, xli, 25.

<sup>9</sup> *Cent. J. Chir.*, 1890, x, 1, 2.

<sup>10</sup> *Br. Med. Journal*, April 5, 1890.

<sup>11</sup> *Medical Press and Circular*, August 20, 1890.

the chronic form long-continued slow drainage at an early date, is at least worthy of a trial, with a reasonable hope of success in a few cases.

(7) The methods which I have described for performing the operation, especially by the lateral route, are at least worthy of a trial, with a view of determining the value of such surgical procedures.

(8) After trephining and tapping of the ventricles, irrigation of the ventricular cavities from side to side, is not only possible, but does no harm. In abscess involving the ventricle, and perhaps in other conditions, it may possibly do good. The fluid used for such irrigation should not contain anything which, if retained and absorbed, might do harm. An artificial cerebro-spinal fluid, or a simple boracic acid solution, would seem to be the best for such use.

(9) Convulsions due to rapid withdrawal of the cerebro-spinal fluid may be checked by the reinjection of an artificial cerebro-spinal fluid, or such other innocuous fluid as the circumstances may make available.

(10) In either irrigation or injection of the ventricles, it is probably desirable that the air should not enter; but such entrance of air does not seem to be productive of mischief.

(11) In hæmorrhage of the lateral ventricles, at least of a traumatic origin, instant trephining and evacuation of the clot should be done, and in a few cases will probably be followed by a cure, unless the injury of the cerebral tissue is such as to be incompatible with life.

#### PLASTIC OPERATIONS IN THE ORAL CAVITY AND OF THE NOSE.

Rötter<sup>8</sup> reports five interesting and novel operations of this character which he has performed while assistant at the Bergmann Klinik in Berlin. In the first case cicatricial contraction had caused such tight closure of the jaws that liquids were taken with difficulty. The cicatricial mass was dissected away from the oral mucous membrane. A flap from the upper arm with pedicle attached was fixed in the resulting defect (by sutures), after bandaging the arm securely to the head, by passing it into the mouth through a verticle slit through the cheek, the epidermal surface toward the cavity of the mouth. On the seventh or ninth day the pedicle was cut. The result was satisfactory.

The second case was a right-sided congenital hare lip and cleft palate of unusual width, complete. The palative cleft was closed by the Langenbeck method, but a defect of about one 1 cm., remained. A flap with a long pedicle was cut from the forehead (Blasius method) and its raw surface grafted with skin (Theirsch) that forming a flap covered on both surfaces with epidermis and capable of resisting moisture. When the flap was ready the right ala nasi was cut through, and the flap was passed through the cleft in the lip into the palative cleft, where it was fastened, its skin-grafted surface being towards the nasal cavity. The pedicle was cut on the eighth day. A good result.

The other three cases were rhino-plastic operations. One was for the correction of a "saddle" nose. Here a skin periosteal-bone flap was cut from the forehead according to the König method as modified by Israel. The healing of this flap was much hastened

by Theirsch grafting. The remaining two cases were for the restoration of noses where the loss was complete. Here the flaps were formed in a similar tissue, but the details of the method are difficult to describe satisfactorily in a review, and the reader is referred to the original article for a full description.

#### OPERATIVE TREATMENT OF CARCINOMA OF THE LOWER LIP.

Zielewicz<sup>9</sup> claims that radical operations, where epithelioma has involved the whole, or a greater part of the lower lip, and where an operation without a plastic involving healthy soft parts is impossible, are contraindicated. He claims that there is always a rapid recurrence so extensive that further operation is impossible. In such cases he prefers the following method: With a galvanic cautery he punctures the growth; a few days later he extirpates the tumor with a galvanic cautery knife.

#### BILLROTH'S OPERATION FOR FISSURES OF THE HARD AND SOFT PALATE.

This method is described by F. Salzer.<sup>10</sup> By preference the operation is delayed till the patient has reached the age of fourteen. Young children are rarely operated upon. The Ferguson incision, for relief of tension, through the muscles of the uvula is discarded and instead the median plate of the pterygoid process is divided subcutaneously at the base of the hamular process. This allows the point of muscular attachment to be displaced inward *en masse*, thus relieving the tension. This has been done in fifteen cases. The operation is done with the patient recumbent and head dependent. The edges of the defect are refreshed, both of hard and soft palate. Hæmorrhage during the operation is controlled by gauze tampons. After the lateral incisions on the outer side of the hard palate along the alveoli, beginning at the second or first bicuspid tooth, and extending to the posterior border of the alveolar process have been made, a chisel is inserted into the posterior angle of this incision against the pterygoid process, and by a few blows in backward and upward directions, the median plate of the pterygoid process of the sphenoid bone is split off. Through prying motions of the chisel or elevator (a safer instrument) it is possible to displace this bone so far inward that the edges of the wound of the soft palate may be brought into apposition. The separation of the bridging flaps of the muco-periosteal covering of the hard palate is done according to the Langenbeck method. In order to approximate the wound edges to each other at the border of the hard and soft palate, it was sometimes necessary to divide the nasal mucous membrane at the posterior edge of the floor of the mouth with Langenbeck's button-tipped scalpel. The sutures are set, two (at the most three) auxiliary sutures (quilted sutures) of the hard and soft palate which bring the median edges of the wound squarely up together, and prevent any tension on the few button sutures applied later. The sutures are inserted with simple straight obtuse curved double-edged needles having the eye in the point, and are partly drawn through by Ferguson's loop method. The sutures are tied. The nose and mouth well irrigated with three per cent. salicylic acid solution. Finally the lateral wound fissures and

<sup>8</sup> Deutsche. med. Wchnschr., 1890, xvi, 25.

<sup>10</sup> Contrib. f. Chir., 1890, No. 13.

<sup>9</sup> Münch. med. Woch., 1889, xxxvi, 39, 31, 32.

cavities are firmly packed each with a small strip of iodoform gauze. This packing is antiseptic and controls hemorrhage. It is of great importance in immobilizing the parts of the palate which have become movable, and relieves tension of sutures. It is therefore left *in situ* ten days. The description of the above operation is somewhat unsatisfactory in regard to anatomical detail, which a later publication will perhaps make more intelligible.

#### RESECTION OF THE LARYNX.

Bardenheuer contributes the following points with reference to this operation, the object of which is to avoid the septic inflammation of the areolar spaces between the trachea and the adjacent muscles, one of the chief dangers of this procedure, and one which caused the death of four cases in his clinic. He recommends that the patient shall be placed in bed in such a position that the head is lower than the trunk, so that wound secretions, food, etc., shall be prevented by gravity from flowing into the trachea or collecting in the cellular spaces above alluded to. He sutures the mucous membrane below the epiglottis to the anterior wall of the œsophagus (that is, the wound edges remaining after the removal of the growth), thus separating by a wall of mucous membrane the œsophagus and pharynx from the wound cavity. In his last two cases it was not necessary to feed through a tube, since deglutition was possible unaided.

#### THE OPERATIVE TREATMENT OF GOITRE.

A valuable article with the above title has been written by W. W. Van Arsedale,<sup>11</sup> which reviews the surgical part of this affection to date. An extensive bibliography is appended. The article is worthy of a careful perusal by those interested in this subject, but too extended to do more than to reprint the writer's résumé on certain points.

In regard to choice of operation for all kinds of goitre, the exophthalmic variety excepted, he concludes: With large nodes in simple goitres, enucleation is preferable; when impracticable, resection. With nodes in immovable growths, where there is some danger of suffocation, enucleation; if the danger increases, *évidement*. With very soft nodes in simple or immovable goitres, *évidement* (for the sake of dispatch). Numerous small nodes, partial extirpation; no sound tissue is present which may be left, resection. Vascular tumors, ligation of arteries; cysts, enucleation. Diffuse hypertrophy, partial extirpation; if no sound tissue is present which may be left, resection. Malignant growths, total extirpation, for which amputation may be substituted. Acute thyroiditis in simple goitre, total extirpation; acute thyroiditis in cystic goitre, enucleation; incision and drainage where despatch is necessary. When the nature of the tumor is unknown, or if the elected operation proves impracticable, resection.

Injections are reserved for cases where for any reason an operation is contraindicated. Of the various fluids in use, namely, tincture of iodine, Lugol's solution, arsenic, ergotine, Fowler's solution, osmic acid, and iodoform; the latter seems most worthy of trial. This is the von Mosetig-Moorhof method, and principally in soft parenchymatous or follicular cases with excellent results.

R. Iodoform . . . . .	1.00
Ether sulph. } Oil olive }	As 7.00

Sig. Dose one to two grammes (15 to 30 minims) every three to eight days. Repeat five to ten times in all.

The indications for operation are: Suffocative symptoms, dyspnoea, (even only after exertion), rapid growth of tumor, difficult deglutition, interference with patient's usefulness or enjoyment of life. Age does not contraindicate an operation.

The complications which may occur during operation are: (1) hemorrhage; (2) gross lesions of the nerves, especially the sympathetic, the pneumogastric, the hypoglossal, and the recurrent laryngeal nerve; (3) injuries to the adjacent organs, especially the œsophagus and the trachea.

Those directly following are: (1) the inflammatory; or (2) septic complications, such as aphonia due to tumefaction of the mucous membrane, and acute suppuration of the visceral space of the neck, with cellulitis and consequent burrowing of pus and anterior mediastinitis.

Among the more remote consequences of thyroidec-tomy are: (1) acute mania following operation; (2) epilepsy; (3) tetany; (4) hysteria; (5) myxœdema; (6) recurrence of malignant tumors *in loco* and elsewhere, with adhesions of the capsule to the growth, envelopment of the large veins of the neck and the nerves in the growth, extension below the sternum, etc.

#### TREATMENT OF CANCEROUS STRICTURES OF THE ŒSOPHAGUS BY CONTINUOUS CATHETERIZATION.

Gangolphe<sup>12</sup> strongly advocates continuous catheterization in the treatment of all cases of cancerous strictures of the œsophagus, and arrives at the following conclusions:

The permanent catheter is especially indicated in recent cases of cancerous stricture of the œsophagus. Even when the respiratory system is invaded, the long, soft catheter can still be employed with advantage, since it absolutely prevents the penetration of food into the bronchi. The existence of abundant hemorrhage, either spontaneous or excited, is a contraindication to frequent catheterization, and sometimes even to the employment of a permanent catheter, although the latter may be used for a considerable time without serious accident.

Short canulas may be used in the early stages of the disease, while the long canulas seem more applicable to the latter periods.

Gastrostomy should be reserved for exceptional cases in which the involvement of neighboring organs, easily excited and frequently repeated hemorrhages, or impossibility of catheterization after repeated efforts, contraindicate the use of a permanent catheter.

(To be continued.)

A. M. VIGNE, a French surgeon, has come to grief over his venture as a novelist. The heroine of his story is a young lady who, by reason of certain abnormal formations should never have got married, but who did so without knowing of her marital incapacity. In describing her, it appears that the doctor depicted with much realism the case of one of his own patients, whose husband has, very properly, prosecuted him for breach of professional confidence. — *Medical Press*.

## Reports of Societies.

### SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

GEORGE H. MONKS, M.D., SECRETARY.

MEETING, Wednesday evening, January 7th, the Chairman, DR. A. T. CABOT, presiding.

DR. F. B. HARRINGTON read a paper called

#### RHEUMATIC FLAT-FOOT.<sup>1</sup>

and showed patients with this affection, who had been treated by him.

In reply to a question as to his method of taking the plaster cast for the sole-plate, Dr. Harrington said: The method I have employed and like better than others is the following: I cut a piece of cloth (preferably cotton-flannel), to the shape of the sole; then, having covered it rather thinly with plaster-of-Paris, I lay it on the foot and hold it in position for five minutes or so, until it is hard enough to retain its shape when removed from the foot. The method has the advantage that one can hold the foot in the desired position, while the plaster is hardening. Of this plaster mould a cast can be taken later, and this cast and the mould sent to the instrument-maker.

DR. S. J. MIXTER: I can hardly agree with everything that Dr. Harrington has said as to the amount of relief afforded this class of patients by a sole-plate. The relief is certainly great; but, as Dr. Harrington says, it takes longer to get it than in most other cases. I want to speak about the traumatic cases which Dr. Harrington has referred to. I do not refer to cases where the ankle has been injured and flat-foot has followed as a result of weakness, but to injuries due to direct falls upon the soles of the feet, or from straining of the plantar ligaments. I have had two or three such cases, which illustrate this point very nicely. One was the case of a farmer in the country who fell from a load of hay, striking squarely on one foot. This accident was followed by the characteristic pain and flat-foot. There was no strain of the ankle, but simply one of the plantar ligaments; but for six or eight months the patient was unable to walk without a crutch or a stout cane, and was thus obliged to give up work almost entirely. In this case, which incidentally needed some slight correction, the plate afforded immense relief.

In another case of mine there was more of a chronic sprain (from mountain-climbing), and perhaps the ligaments were more strained than sprained. The patient was a young man of twenty years. He was unable to walk across his room in the morning without putting on half-boots. He could not do it in his bare feet. In this case there was no sign of flat foot to be seen, but the symptoms were perfectly characteristic. There was pain in those parts of the foot where we usually find it in flat-foot. In this case, after several trials, plates were fitted, and the patient walked about as well as he could before the trouble came on. He could walk long distances, and regained his usual good health and strength which had been impaired by a long stay indoors. It is in these cases that we meet with the most brilliant results.

DR. W. N. BULLARD: I would like to say one word in regard to the diagnosis of these cases, of which we see many in my department at the Boston Dispen-

sary where we receive all cases of suspected rheumatism. There are four forms of pain referred to the sole of the foot, aside from those due to purely surgical conditions. Of these, the rarest is the pure neuralgic form, the so-called erythromelalgia of Mitchell. There are the two rheumatic forms, the true plantar rheumatism, and that due to or connected with gonorrhoea, and lastly, the true flat-foot with which in many cases a certain amount of muscular trouble (rheumatic so-called), often co-exists. It is this latter form which has been discussed to-night. This is due to weakening of the arch of the foot from any cause and may occur not only in cases where the arch has given way or is naturally slight, so that the patient appears flat-footed, but also, and not very infrequently, in cases where the arch is normally or even at times rather more than usually, high. In such cases the diagnosis is not always easy, but can be made only after careful examination. The crucial test is the relief of pain by the use of a flat-foot plate.

One point in regard to flat-foot cases not yet mentioned, is the frequent occurrence of a pain in the calf of the leg. This is common, and frequently is the first symptom which calls attention to the strain on the arch.

Increased knee-jerk is liable to occur in all cases of irritation, inflammation or pain in a limb otherwise normal, and hence naturally occurs in flat-foot. Beyond this it has no diagnostic significance.

DR. J. W. ELLIOT: I have noticed in the out-patient department cases of ordinary fractures of the leg which are followed by flat-foot for a few months; a condition which in this class of cases seems to be very easily cured.

DR. HARRINGTON: The pain in the calf of the leg has been spoken of as one of the symptoms in flat-foot. This I have observed; and I have also seen in a case of flat-foot a symptom which I have neither heard of nor seen mentioned, and that is, pain in the knee. At the time I did not suppose this was the result of the flat-foot; but, after curing the flat-foot, the pain in the knee entirely disappeared. I suppose the pain was due to an unnatural strain on the ligaments of the knee. The special point I want to make is to show the necessity for watching these acute cases in the first attempts to walk about, and preventing straining or stretching of the ligaments. If the cases are rheumatic they must be treated for rheumatism, and in this way we can help such patients considerably.

DR. R. W. LOVETT showed a male child eighteen months old, illustrating the

#### SPONTANEOUS CURE OF A SPINA-BIFIDA,

and said that the child was born with a tumor in the lumbar region which has disappeared, to give place to a dense and puckered scar as large round as a teacup. The history of the case is obscure, and one must depend largely upon the physical signs.

From time to time leakage of spinal fluid occurs from the cicatrix without apparent effect upon the general condition. The legs are partly paralyzed and the child has never walked. It appears to be a spontaneous cure by rupture of the sac with implication of the nerves in the cicatrix.

DR. BRADFORD read a paper on

#### TWO CASES OF SPINA-BIFIDA.<sup>2</sup>

<sup>1</sup> See page 351 of the Journal.

<sup>2</sup> See page 352 of the Journal.

DR. LOVETT: I have had some experience in the treatment of spina-bifida with Morton's fluid. A boy about six years old, came to the hospital with a spina-bifida about the size of an infant's head. He had serious paralysis. He could not walk. It was perfectly evident from an examination of the sac that the cord was involved; so the idea of operative interference did not come into the question. I injected him six times with Morton's fluid. In two months his condition was so much improved that he could walk without assistance. Whether that was due to his good care while in the hospital, or to the fluid injected, I do not know. There was no change in the size of the tumor. The patient has continued improved ever since.

Morton's fluid can be drawn into an ordinary hypodermic syringe. It is diluted one-half or two-thirds. If one uses a large nozzle there is danger of leakage. In this case there was some leakage for two or three hours. Last May there was a little ulceration at the apex of the tumor, and it discharged gradually for some weeks.

DR. J. C. WARREN: In my experience the cases suitable for operative treatment are the exception. In most of the cases that I have seen the sacs were very much distended, serous looking membranes, which seemed to put the matter of operative interference out of the question. Occasionally one sees cases which seem favorable for treatment,—such a case as the following: A child, eight months old, otherwise healthy, had a tumor the size of a silver dollar, translucent, in the lower dorsal region. There was nothing to be seen or felt in the sac. The operation was that of subcutaneous ligature. Catgut was passed around between the sac and skin, two openings being made in the sac for this purpose at its base on the median line. The ligature was tightened and then a clear fluid was drawn off. An antiseptic dressing was applied. The sac refilled and became very tense, and the tumor was aspirated and a turbid fluid was drawn off. Ten days after operation it was aspirated again and not nearly as much fluid as before was removed. Fifteen or twenty-one days after this the sac discharged a fluid like pus. The child had convulsions. The sac was then opened and cut off. The interior seemed to be entirely shut off from the canal, the opening being covered with fibrous tissue. The patient died three weeks after the first operation. I felt that the lower opening which admitted the ligature was very difficult to keep aseptic. It might have been better to have passed the ligature transversely instead of longitudinally, and thus keep it as far away as possible from the anus. If I had the case to treat over again, I should strongly favor laying the sac open in the beginning, paring away the covering of the sac as much as possible, ligaturing the pedicle and sealing the wound with colloidum.

DR. HOMER GAGE, of Worcester: Though I saw the case Dr. Warren has just reported, I have but little to add. It seemed to me at the time a very favorable case for operation, and I was surprised at the absolutely complete closure of the sac at the second operation. At that time the outlook for the case was certainly most favorable. Dr. Gage then reported another case of spina-bifida.

The CHAIRMAN said that cases of spina-bifida varied very greatly in their pathological conditions, and that these conditions not only made very great differences

in the success of operations, but should, in many cases, determine the kind of operation applicable to the case.

They vary all the way from a unilocular cyst joined to the spinal cord by a single opening; through various degrees of multilocular cystic development to a condition which resembles more closely the lymphangiomata as seen in the skin than any other morbid process. It is to be remembered that the arachnoid space in the spinal cord is a lymph space, and that these tumors are, therefore, all of them, dilated lymph spaces, varying in their form but not in their essential pathological condition.

It is in the cases which resemble lymphangiomata that surgical interference is most successful. In them the opening into the spinal cord is a small one, and can usually be closed by a clamp while the wound is thoroughly and closely stitched, and thus the too free escape of the spinal fluid may be prevented. In many of the multilocular varieties this can also be accomplished. When we reach a unilocular condition, particularly where the walls of the cyst are very thin this operative plan is much less successful, and it is in these cases that the injection of Morton's fluid would appear to be the more appropriate treatment.

The Chairman said that he had operated in three cases. In one, which approached the lymphangiomata in its pathological condition, he had obtained a cure by clamping the tumor so as to close the opening into the spinal cord, cutting off the tumor beyond the clamp, and stitching the skin and deep parts closely together so as to prevent the escape of fluid from the spinal cord.

In the second, in which the tumor was multilocular, and of very large size, he followed the same plan, and although the patient seemed to do well for two or three days, at the end of that time he died suddenly without warning, probably from meningitis.

The third case was another instance of cystic condition in which there was but one cyst. He injected the tumor with Morton's fluid, and in that case the child left the hospital before the result was finally known. At the time the child left it had a very high temperature, and it seemed doubtful whether it would survive, although it was then seventeen or eighteen days after the operation.

#### PRIMARY CANCER OF THE KIDNEY.

DR. J. C. HARRIS, of Lowell, presented a specimen of a kidney removed by abdominal section. Pathological examination of the specimen had proved the existence of cancer. The following history of the case was given:

Mrs. S., Nashua, N. H., age forty-nine, has, during the past six months, occasionally had slight attacks of hæmaturia. In November, 1890, she suffered from a severe attack, which was followed by a second in December. From both, the suffering and loss of blood were very great, and Mrs. S. was much prostrated. Her attending physician, Dr. Wallace, found a slightly movable hard mass in the right abdominal cavity, just below the liver which he diagnosed as a tumor of the right kidney, and the source of the hæmorrhage, which, already had so seriously exhausted his patient.

January 10, 1891, with his assistance and that of Drs. McQuesten, Dutton, Hammond and Kittredge, I made an incision through the abdominal parietes, over the growth, separating from it the overlying

intestines and omentum, and incising the posterior peritoneum which was quite closely adherent to the tumor. The vessels of the kidney were ligated *en masse*, and made a good pedicle, which admitted of considerable stretching, and was easily secured. On the whole, the operation was not attended with any great difficulty.

At this time, five days after the operation, patient's temperature and pulse are normal. She passes about thirty ounces of urine in twenty-four hours.<sup>3</sup>

This specimen in weight is about eight times that of the normal kidney. A growth distinct from the kidney tissue had started from the pelvis and had pushed its way directly through the kidney substance and formed a prominence upon one side.

Dr. R. H. Fitz sends me the following report: "The new formation in the kidney and its pelvis is composed of an alveolar structure, in which are masses of large epithelioid cells. In places the alveoli are so elongated as to suggest sections of renal tubules, but they are wider, and the contained cells are three or four times as large as the epithelium of the straight tubules. The structure is that of cancer."

The specimen, therefore, is an example of that very rare affection, primary cancer of the kidney.

DR. ELLIOT presented a

#### SPECIMEN OF AN APPENDIX

removed a week ago. The appendix was about four and a half inches long, and about the size of the thumb. This was removed from a man aged thirty-five years. The operation was done on the fourth day. On the third day the temperature and pulse were normal. On the fourth day the temperature was 100°, the pulse 84, the abdomen was very tense and tympanitic. There was no vomiting, and the patient looked very well.

DR. A. K. STONE showed an

#### ARNOLD STERILIZER,

and stated that it was probably the best practical sterilizer for surgical use in the market. He had made experiments as to the length of time necessary to leave instruments in the sterilizer; and found that *five minutes* was sufficiently long to destroy all ordinary forms of bacteria. He said this was important, inasmuch as many believed it took a much longer time.

DR. E. W. CUSHING presented

#### A UTERUS REMOVED FOR CANCER.

In the upper part of the specimen was to be seen and felt a distinct nodule of cancerous disease.

#### NEW YORK COUNTY MEDICAL ASSOCIATION.

STATED Meeting March 16, 1891, the President, S. B. W. McLEOD, M.D., in the chair.

DR. J. HILGARD TYNDALE read a paper on

#### TREATMENT OF THE VARIOUS FORMS OF PULMONARY CONSUMPTION BY INOCULATION WITH VACCINE LYMPH, WITH PRESENTATION OF CASES.

Having referred to the various pathological processes met with in phthisis, he said that really active destruction began only with the advent, proliferation

and dissemination of the tubercle bacillus. The points included in his method of treatment were the following:

1. Exact and localized diagnosis. No cases, he said, of pure connective-tissue proliferation, nor of general or localized cirrhosis of the lung (in other words peribronchitis), and no cases of purely mechanical disturbances of respiration, caused by the binding down of lung tissue by pleuritic adhesions, nor cases in which diffused dry sibilant râles, heard all over the chest, distinctly point to obstruction in the upper air-passages, were suitable for this plan of treatment. The cases to be selected for inoculation were those in which are found more or less active cavities and infiltrations, with suppurative expectoration, and with or without the presence of the bacillus, coupled to a not entirely hopeless general condition.

II. Inoculation with pure vaccine lymph obtained from the cow. This came in capillary tubes containing about two drops each, and this quantity was generally employed for one injection. As a solvent he used fifteen drops of distilled water, with the addition of one drop of pure glycerine. The fluid was injected subcutaneously near the seat of the trouble, by means of an ordinary hypodermic syringe, which was afterwards cleansed by hot water and absolute alcohol. At the third and fourth injections the contents of two tubes were frequently used. The injections were made at first at intervals of from six to eight days; but when the bacilli had disappeared and the expectoration became sparse and of a mucus character, it was his practice to inject only once in every two, three or four weeks. No violent reaction followed the injections, but the temperature usually rose from one to two degrees in the course of from eight to twenty hours, and more or less frontal headache was apt to be experienced.

As was well-known, the actual losses from the body (if he might be permitted to call them so) to which the consumptive patient was subject, were somewhat as follows: (1) Fever; (2) expectoration—important as to its quality and quantity; (3) night-sweats; (4) loss of appetite; (5) loss of muscular strength; (6) diarrhoea; (7) cough—as a peripheral irritation and resulting in loss of sleep; (8) fulness and rapidity of the heart's action, leading to exhaustion of the cardiac muscular tissue; (9) fluor albus in women. All these manifestations were favorably influenced by the inoculation, some at once, and others more gradually. The treatment, once commenced, should be steadily persisted in. Even if the results were small in the beginning, it would not infrequently be found that all at once a point would be reached at which the scales turned in favor of recovery.

III. Blood and fat formation. This line of treatment should be inaugurated at the earliest possible moment.

IV. Lung gymnastics, consisting of five deep inspirations made every twenty minutes throughout the day.

V. The removal of obstructions to inspiration or of causes of irritation in the upper air-passages. Such removal of obstruction should be made as soon as the patient began to show signs of improvement.

Dr. Tyndale thought that all *symptomatic* treatment in pulmonary consumption should be abolished, except for temporary relief in cases of great urgency. He favored all supporting treatment—such as the

<sup>3</sup> Patient has since entirely recovered and remains perfectly well.

use of cod-liver oil, iron, malt, the hypophosphites, bichloride of mercury, arsenic, creosote and diet—provided the agents employed were not indiscriminately prescribed, but used in accordance with the requirements of each individual case. As regards the presence of tubercle bacilli, it was a question of very great importance whether the bacilli were localized or not, whether they remained in their original seat or had become diffused. If they had become generally disseminated throughout the lung substance, the limit of our therapeutic possibilities had been reached. We could successfully eliminate local tuberculosis, but up to the present time the line was drawn at general dissemination of the bacilli, a condition usually manifested by a general bronchiolitis.

It seemed evident to him that in the inoculation of animal virus or intensely poisonous chemicals in very minute doses, we were now on the right track in the treatment of consumption. We now had Professor Koch's tuberculin, Professor Liebreich's cantharidate of potash, Dr. J. Blake White's chloride of gold and manganese, and lastly the bovine vaccine virus. Hypodermic injection appeared to be the accepted method for the introduction of these remedies into the system. As to the manner in which these agents acted, we could only at present indulge in idle speculations. His own belief was that more than one animal and chemical virus would be found to accomplish the same object, and that the secret of the whole matter lay in a correct diagnosis and the adaptation of the remedy to the individual case.

Dr. Tyndale then exhibited nine patients—seven males and two females—all of whom had been the subjects of phthisis, and showed the presence of the tubercle bacillus, and many of whom had cavities in the lungs. In most of these the special treatment by the vaccine inoculations had now been discontinued, the bacillus having disappeared from the sputa (in cases where any expectoration remained) and the signs of active tuberculosis no longer being present. Two or three of the cases were still under the injection treatment.

Dr. KRETCHMAR, of Brooklyn, said that he had as yet had no personal experience with this method, and he thought that certain questions would have to be answered by Dr. Tyndale before the value of his investigations would be generally accepted. In the first place, he should like to inquire what statistics the doctor had to present in support of his treatment. He had shown to-night nine cases, and it was desirable to know what they represented in the total number of his cases.

To this Dr. TYNDALE replied that he had employed the treatment altogether in twenty-three cases, all selected by himself, and that the remaining fourteen all showed the same well-marked signs of improvement that those presented this evening did.

Dr. KRETCHMAR next inquired what it was that had induced him to make trial of vaccine lymph in the treatment of tuberculosis.

Dr. TYNDALE replied that it was simply an experiment, and not based upon any special theory.

Dr. KRETCHMAR then inquired how many examinations of the sputa for bacilli were made in his cases.

Dr. TYNDALE replied that it was his practice to have two examinations made each week for a period of five weeks; after which the examinations were made once

a week unless this became impossible on account of the absence of expectoration.

Dr. KRETCHMAR went on to say that the results claimed by Dr. Tyndale were certainly such as to call for further investigation of his method. He had personally tested Koch's tuberculin in six cases, and his results were by no means as favorable as those of Dr. Tyndale, since only one of the patients could be reported as highly improved. In view, therefore, of these very gratifying results in the limited number of cases experimented with, he thought it highly desirable that the profession should have the opportunity of judging of the value of the new method after it had been used in a larger number of cases and for a more extended period of time. The trouble with these walking cases of phthisis in hospital and dispensary practice was that they were so apt to become lost sight of.

Dr. J. BLAKE WHITE said that while, like Dr. Kretchmar, he had no personal experience with Dr. Tyndale's method, he had made many experiments with other kinds of injection material. He had been exceedingly pleased with the paper, and he agreed with its author in the opinion that the experiments now being made with various substances in the treatment of tuberculosis constituted an advance in the right direction; so that the ultimate results of such investigations would be of very great service. Because we could not at once understand the manner in which new methods of treatment acted, was no reason why we should regard them contemptuously or with disfavor. As to Dr. Tyndale's method, he would certainly take the earliest opportunity to try it and to compare the results met with, with those obtained from other methods. It would seem probable, as far as we could judge at present, that in this and other recent treatments by hypodermic injection, a process was set up in the system which had the effect of holding the tubercular process in abeyance.

Dr. PAUL GIBIER, having inquired of Dr. Tyndale, if he had made any experiments upon animals before he had tried the vaccine lymph treatment on human subjects, and having been answered in the negative, said that Dr. Tyndale was certainly very lucky in achieving such very successful results as he had reported without having made any preparatory experiments. He was lucky because so far it had never been claimed that vaccine lymph could be made a remedy antagonistic to tuberculosis. So far from this, it had always been recommended that the virus used for ordinary vaccination should be taken only from very sound animals, and it had been suggested with apparently good reason that the lymph for vaccinations should be taken from the horse, or, best of all, from the goat, as these animals were much less subject to tuberculosis than the bovine race. The vaccine virus had more than once been accused of introducing tuberculosis into the system, as it was certainly a well-established fact that syphilis had been thus introduced. One objection to Dr. Tyndale's method, he thought, was the difficulty of obtaining vaccine lymph perfectly pure, and consequently it might perhaps produce abscesses, which would be more severe than those sometimes caused by the lymph when the lancet was used. It seemed to him highly desirable that the method of treatment advocated by Dr. Tyndale should be confirmed by experiments on animals. In conclusion he remarked that while the vaccine injections were being used, support-

ing treatment of cod-liver oil and other agents was also employed.

DR. TYNDALE explained that he never commenced the supporting treatment until the local signs of tuberculosis were entirely gone. As soon as this stage had been reached such treatment was resorted to with great advantage.

DR. JOHN G. TRUAX asked if the patients had all been vaccinated before, and Dr. Tyndale stated that they had.

Dr. Truax then asked if abscesses had ever resulted from the treatment, and also if the constitutional symptoms were marked after the injections.

DR. TYNDALE replied that the only constitutional symptoms, as he had mentioned in the paper, were gradually rising temperature and headache more or less marked, and even these were frequently absent. He had never seen abscesses caused by the treatment.

DR. TRUAX said he had found that in a large percentage of instances, vaccination when repeated would take for a second or third time.

DR. TYNDALE said that when he first commenced the vaccine lymph treatment of tuberculosis, he introduced the virus by scarifying the skin as in ordinary vaccination, and that the usual effect was often noticed. No such effect, however, was produced when the virus was injected by means of a hypodermic syringe.

DR. TRUAX went on to say that the results reported by Dr. Tyndale certainly seemed to be most successful. The presence of the tubercle bacillus in his cases showed that there was no room for doubt as to the diagnosis, and he thought, therefore, that the method should be given a trial by all who had the opportunity to test it.

DR. E. V. AGRAMONTE thought that Dr. Tyndale's results were better than any that had thus far been reported. Judging from the present condition of the patients whom he had presented this evening, his success seemed to him wonderful.

DR. GIBIER said that Dr. Tyndale would be sure to meet with great skepticism as to the value of his method, but if he were right the truth would be ultimately made known to all. There was one fact to which he had neglected to call attention when he was speaking before, namely: That many physicians find that patients who have been vaccinated perhaps a number of times contract tuberculosis and die from it. Vaccination, he thought, had many analogies to the second stage of syphilis.

In reply to a question by a member as to the significance of loss or gain in body weight, Dr. TYNDALE said that he cared nothing whatever for weight in itself. Of course, a large decrease in weight might indicate serious trouble, but this was always accompanied by other symptoms which were more definite and reliable.

DR. E. F. BRUSH read a paper on

#### STERILIZED MILK,

in which he objected to the sterilization of milk for infants' food, because the process devitalized it. Among the other ways in which the value of milk was lessened by sterilization, he said, was that the soluble albumen was made insoluble. He believed that a child raised on sterilized milk would be less robust, and have a constitution that would more readily succumb to deleterious influences than one fed on natural milk. He contended that every human being required some living

food, and that the cause of scurvy was deprivation of such living food. The sterilization of milk for adults was of but little consequence, as they had other kinds of food; but it became a matter of the highest importance to an infant whose only food was milk. The true remedy for the evils that sterilization of milk was designed to obviate, he said, was to be found in reform in the dairy. It was the cow herself that should be sterilized. It was not enough that all the sanitary conditions should be as perfect as possible, or that the greatest possible care should be used in regard to the milk; but the removal of the ovaries would remove many of the objections complained of, and he hoped to live to see the day when every dairy supplying milk for infants should consist entirely of spayed cows. At the present time, however, abortions were common in the dairy, and the milk necessarily suffered from the frequently unfavorable condition of the cows.

### Recent Literature.

*On Aphasia, or Loss of Speech, and the Localization of the Faculty of Articulate Language.* By FREDERIC BATEMAN, M.D., F.R.C.P., etc. Second edition, greatly enlarged; 8vo, pp. 420; with four illustrations. London: J. & A. Churchill. 1890.

The first edition of this work won some reputation twenty years ago as one of the earliest English treatises on the subject. The present edition is an example of the effect of putting a small amount of new wine into an old bottle, with the usual result. Since the first edition appeared we have had the works of Kussmaul, Wernicke, Lichtheim, Seppilli, Ross, Bernard, Namyn, and Starr, and, after a careful examination of the work before us we can see not the slightest reason for its existence. The bulk of the work is made up of the theories and ideas of twenty years ago, to which are added various bits gathered from modern works. The first hundred pages are devoted to an alleged bibliography, admittedly retained from the first edition, but without any addition of cases accurately observed, or autopsies where the lesion was exactly defined, such as our present knowledge demands. Then comes a collection of cases observed by the writer himself, where he apologizes for too detailed reports, and then gives a case of probable hysterical mutism, which he calls "epileptic logoneurosis," excludes hysteria because it is rare in the male, and gives no information as to the presence of the hysterical stigmata, this case occurring in 1884. Another case of undoubted general paralysis is cited, without a microscopical report, to show that speech disturbances may occur without changes in the frontal lobes. The rest of the book the author regards as a new work, rather than a revised edition of the former one. It seems, however, still based on the knowledge of twenty years ago, with much matter introduced in a discursive fashion, partly relating to speech, and partly to criminal anthropology, the causes of right-handedness, the deterioration of the race, etc. The writer finally concludes that there is no absolutely localized centre for speech, but the work fails utterly to present the modern views of the physiology or pathology of speech, or to give any definite or clear ideas which can enable the practitioner to examine a case of aphasia scientifically, or to get any comprehensive notion of the subject.

THE BOSTON  
Medical and Surgical Journal.

THURSDAY, APRIL 9, 1891.

*A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.*

*SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.*

*All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.*

DAMRELL & UPHAM,  
283 WASHINGTON STREET, BOSTON, MASS.

ANNUAL REPORT OF THE BOSTON BOARD  
OF HEALTH.

THE annual report of the Health Department of the City of Boston, for 1890, contains much interesting matter and many concise and valuable tables and charts. The health of the city is exceptionally good, the death-rate for the year being lower than that of any year since 1885, notwithstanding the high rate during the epidemic of influenza. The deaths numbered 10,181, which with a population of 448,477, as given by the national census, makes the year's death-rate 22.70 per thousand. The rate for the preceding year was 21.12, and the average for the past ten years 23.47. This decrease is especially noteworthy from the fact that at the beginning of the year the mortality was extraordinarily high on account of the epidemic of influenza, which was held responsible for 550 deaths, increasing the death-rate in January to a point unknown before in the city's history. The deaths from acute diseases of the respiratory organs for the first two weeks were 121 and 148, whereas during the same weeks in 1889 the numbers were 29 and 20. It is of interest to note that while the small-pox epidemic of 1872-73 caused 1,679 deaths in Massachusetts in about two years, this recent epidemic of influenza, in fifty days, caused an increase of 2,500 in the number of deaths. The decrease in last year's mortality is chiefly due to the small number of deaths from the zymotic diseases, the percentage of deaths being but 16.47 as compared with an average of 22.31 per cent. during the past ten years. There has also been a decrease in the infant mortality. The number of cases of contagious disease reported was 4,370, with 617 deaths, as against 5,758 cases with 823 deaths, the preceding year. There was one case of small-pox, but no death. It is noted that the deaths from consumption have been proportionally decreasing during the past forty years, while those from pneumonia, heart-disease and bronchitis have increased. The table giving a list of diseases assigned as the cause of death suggests, in some places, as similar tables so often do,

either a lack of care on the part of physicians in making out death-certificates, or failure in diagnosis. There are, for instance, 600 deaths recorded as due to heart-disease, unclassified.

Concerning schoolhouses the Board says that the questions of light, heat, ventilation, question of infection, and whether to send a child home or readmit him, should be settled on the spot from day to day, by a competent judge, for which purpose they propose to ask for \$10,000 this year to secure the services of fifty young physicians to aid in the work.

Urged by a letter from Prof. C. P. Lyman of the Harvard Veterinary School, in which the increase of rabies in dogs in this vicinity is pointed out, the Board have held a conference with the Board of Cattle Commissioners, with the result that the latter board have ordered boards of health to take the same course for the suppression of rabies as for the suppression of other contagious diseases among domestic animals, and to cause all suspected dogs to be at once quarantined, or securely held in restraint till destroyed or released by order of the Cattle Commissioners.

The subject of garbage is discussed, and a system recommended by which it could be burned in the kitchen where it first appears as waste, by the introduction of proper apparatus.

The report of Dr. John H. McCollom, Physician to the Board, contains, among other matter, charts showing the prevalence of diphtheria and scarlet fever during the different months of the year. These charts show beautifully that the number of cases increases during the time that the schools are in session and diminishes during vacation, showing the paramount importance of a careful medical supervision of the schools. The author says that there is no doubt that the prevalence of diphtheria and scarlet fever is due largely to the fact that many children attend school while they are ill with mild and unrecognized attacks of these diseases, and thus form innumerable sources of contagion. It is futile to attempt to absolutely stamp out any contagious disease by removal to the hospital and disinfection, as long as there are so many unrecognized cases in daily attendance at the schools and in places of public resort.

TUBERCULOSIS IN MEAT.

In his report to the Boston City Board of Health, Alexander Burr, M.D.V., gives the results of his work at the Brighton Abattoir, especially in regard to tuberculosis. He hopes that the time will soon come when all cases of tuberculosis may be condemned, for recent experiments with tuberculous beef prove that the flesh contains the bacillus as well as the pulmonary and glandular tissue. Again, even if it is confined to the glandular tissue, as some suppose, and the flesh perfectly healthy, the smaller glands are so distributed throughout the body that it would be impossible to dress the animal without still leaving some tuberculous glandular tissue.

He has made it a rule to condemn all animals showing lesions on the pleura and peritoneum, irrespective of the extent of the pulmonary lesions. This may seem mild to the profession, but when it is taken into consideration that all cannot be condemned, and that the above lesions, in the form of tubercles, lie next to the flesh and are eaten by the community as so much fat, it will be seen that it is a good basis to work on at the present time.

A table of the number and percentages of tuberculous animals shows that Western cattle are very free from the disease. The Massachusetts cow has been severely maligned by some writers, and Dr. Burr proves that she is no worse than her kind in the neighboring States. But he says, that, although the percentage of tuberculosis in cattle of the United States is very small, nevertheless, when cows from the Eastern States are examined, a more serious state of affairs is exposed; but when the condition of the old, unthrifty cows in the city and neighborhood is studied, and the class of people to whom their milk and other products are distributed are taken into account, the subject becomes a very serious one, and well worth the immediate attention of our health authorities. As a prevention of the above dangers, he advises the examination of all milk herds in the city and State semi-annually, and the condemning of such as show lesions of tuberculosis.

#### THE CONDITIONS OF THE PROPAGATION OF DIPHTHERIA.

THE interest which ever centres in this disease, its increasing frequency and its fatality, constitute our excuse for again reverting to this subject.

The microbial origin of diphtheria was affirmed as early as 1861 by Laboulbène, who described parasites which he had found in the false membranes; and at a later day, Letzerich, Talamon and Quinquand called attention to certain bacteria to which they attributed the origin of this disease. It was not, however, till the researches of Klebs in 1883, and those of Löffler the year following, that any precise data were advanced respecting the specific contagion of diphtheria. Klebs discovered a peculiar microorganism in diphtheritic membranes; and this was described with more precision by Löffler, who succeeded in isolating and cultivating it, and with the products of a pure culture he inoculated animals, reproducing in them a disease strikingly resembling diphtheria. In no case, however, did Löffler note the supervention of paralysis.

Löffler's memoir, published in 1884, is a model of the caution and reserve which should characterize a scientific treatise; he had failed to find the bacillus of Klebs in certain typical cases of diphtheria, he had found a bacillus just like this in the mouth of a healthy child. This experimentation was continued by Roux and Gersin, who announced in 1888 that they had detected Klebs's bacillus in all the cases which they had studied; and after having reproduced the disease in

animals (fowls, pigeons, guinea-pigs and hares) by the inoculation of pure cultures, they have in several instances witnessed paralysis similar to what is observed in man as a sequel of diphtheria. They have finally proved that these cultures contain a poison (ptomaine) which, according to the dose, kills the animals rapidly or gives them paralysis. They have also shown that the bacillus does not develop on a healthy mucous membrane, and that to obtain a false membrane it is necessary to irritate the mucous surface, or better still, to excoriate it or deprive it of its epithelium.

The persistence of the virulence of Klebs's bacillus has also been shown by these experimenters. A culture in bouillon kept six months from the light in a closed tube, when sown anew, gave strong healthy colonies, which when inoculated in guinea-pigs and hares, proved to be exceedingly virulent. A culture in serum, kept five months from the light, in a tube stopped with wadding (which, of course, did not exclude the air), had a feeble virulence, but when sown in a new culture field, recovered all of its original activity.

Sevestre, from whose just published "*Études de Clinique Infantile*" we have borrowed, cites from his own experience and that of his colleagues, cases tending to prove the extraordinary vitality of the contagion of diphtheria. A young girl at Passy contracted diphtheria from handling clothes worn by her mother two years before during an attack of diphtheria, and which had not been disinfected. Worms<sup>1</sup> relates the case of a man who when suffering from a simple attack of quinsy, painted his throat with an old camel's-hair pencil, which he had taken, wrapped up in paper, out of a drawer. This pencil had been used four years before to make applications to the throat of a child sick with diphtheria, and by using it the man contracted the disease.

Other instances of a similar kind are on record. One, related by Dr. Grellet, of Algiers, attributes with some probability the derivation of the contagion in a fatal case, to the occupancy by the patient of a room where seven years before three children had died of diphtheria; the room had not subsequently been cleansed, whitewashed or papered. A more remarkable case still, is recorded by Dr. Legrand, and cited by Sevestre. An epidemic of diphtheria broke out in a village of Normandy, and the contagion was traced to a boy fourteen years of age, who was the first to come down with the disease. This boy was the son of a grave-digger, and had a few days before the onset of his sickness been employed with his father in digging up and removing to another part of the cemetery the bodies of a number of persons (mostly children) who, twenty-three years before had died of diphtheria. In this instance, if the disease was thus contracted, the germs of the disease must have remained dormant during all these years, ready to manifest their pathogenic presence, to develop and multiply, when the favorable conditions appeared.

<sup>1</sup> Bulletin Medical, February 20, 1889.

In a previous number of the JOURNAL<sup>2</sup> we have alluded to similar facts recorded by other observers; and if we have again returned to the subject, it is because we regard it as one of great importance from the point of view of prophylaxis. If the diphtheritic bacillus or its germ possesses such enduring vitality and virulence, how painstaking and thorough ought all measures of isolation and disinfection to be when it is a question how to stamp out an existing epidemic, or how most effectually to prevent any after-mischief?

The direct transmission of the disease by the false membrane has been observed again and again; and physicians and nurses who are compelled to make local applications to the throats of their diphtheritic patients cannot be too careful not to be infected by receiving into their eyes, nose, or mouth, fragments of diphtheritic patches which patients in their struggles or fits of coughing may expel.

Can diphtheria be carried in the clothing? From what has been said above of the vitality of the virus, one would be disposed *a priori* to give an affirmative answer to this question, and the facts justify such answer. Sevestre relates the history of a patient in his service at St. Antoine who took diphtheria when recovering from typhoid fever. This patient's sister, an attendant in the diphtheria wards of Trousseau Hospital, had visited the patient a few days previously and had left with him her shawl. This (Sevestre thinks) was without doubt, the cause of the contagion. Cases of the same kind are related by Salter and others. That diphtheria is also communicated by contact with a person who has had this disease, even during the period of convalescence, when no false membranes any longer exist, unless through the clothing, may be regarded as doubtful.

As to whether the contagion may infect the expired air: there certainly seems no reason to doubt that a patient suffering from croup or diphtheria may during fits of coughing expel particles of false membrane or minute portions of mucus, which may for a time remain suspended in the air of the room and render it infectious. It is, however, proved that the contagion of diphtheria is but little diffusible, and that, as a rule, in order for contagion to be imparted, there must be contact between the sick person and the person to be infected. Lanery, Bard and Bretonneau insist on this proposition; and instances are sufficiently numerous where the disease has attacked all the members of one family and spared the neighboring families, where it has prevailed in one part of a tenement and spared the family living in the other part.

Within a few years, numerous facts have been published assigning to diphtheria, a near kinship if not identity with a disease prevalent among fowls (the *pip* or *pepie*), and it has been argued with some plausibility (memoirs of Wolff, Nieate, Paulinis, Delthel, Turner, Menzies, Feissier) that diphtheria in the human subject is often contracted from the fowl. It is hard to gainsay the facts published by the above-

mentioned observers, and instances of the kind are accumulating.

At what time does diphtheria begin, and when does it cease to be contagious? Bard says from the very first day of its appearance, before the formation of false membranes, even; and he cites facts to prove its contagiousness all through convalescence, till the thirty-fourth and fortieth day. Ogle knew a child, convalescent from diphtheria, after a month of quarantine and a return to school, to give diphtheria to nine of its playmates. It is probable that in this case and those of Bard, the germs had remained in the clothing, and that had suitable disinfection been practised early, the communication of the disease would have been prevented. It is to be inferred, from all that we know about the contagion of diphtheria, that the patient ceases to produce germs after the active manifestations of the disease have ceased.

### MEDICAL NOTES.

**HYPNOTISM IN PUBLIC FORBIDDEN.**—The Common Council of Cincinnati has adopted an ordinance making public exhibitions of hypnotism misdemeanors.

**PHILADELPHIA POLYCLINIC HOSPITAL.**—The opening exercises of the new Polyclinic Hospital, at Eighteenth and Lombard Streets, Philadelphia, took place, April 2d, in the presence of a large audience.

**INFLUENZA.**—During the past week the cities of Pittsburgh and Allegheny, Pa., have suffered severely from the epidemic. Sporadic cases have occurred in various parts of Italy during the last few months, and the disease has lately assumed the character of a mild epidemic in Milan.

**LECTURER ON ORTHOPEDICS IN THE JEFFERSON MEDICAL COLLEGE.**—Dr. H. Augustus Wilson, Professor of General and Orthopedic Surgery in the Philadelphia Polyclinic and College for Graduates in Medicine, has been elected Lecturer on Orthopedics in the Jefferson Medical College and Surgeon in charge of the Orthopedic Department of the Jefferson Medical College Hospital, in the place of Dr. O. H. Allis, resigned.

**MEETING OF REPRESENTATIVES OF DIFFERENT LICENSING BOARDS.**—At the suggestion of Dr. William Perry Watson, Secretary of the New Jersey Board of Medical Examiners, Dr. Rauch has called a meeting of one or more representatives of the various medical licensing boards in the United States, to be held in Washington, D. C., on May 6th, at the time of the meeting of the American Medical Association, in order to effect a permanent organization and to make their rules and examinations as uniform as possible. Licensing boards now control medical practice in twenty-one States.

**LEPROSY IN BRITISH COLUMBIA.**—It is reported that the medical men detailed to investigate the cases of leprosy recently discovered at Victoria, have pronounced it of Oriental origin. Immediate steps will

<sup>2</sup> See page 1 of the Journal.

be taken to hunt up the afflicted Chinamen, and return them to China. It is stated that within the past year the disease has made great headway in the Pacific province, and that it has reached a point that will imperil the settlement of British Columbia unless the Government take immediate steps to wipe it out.

**TYPHOID FEVER AT FLORENCE.**—An official notice has been issued by the Foreign Office to the effect that the epidemic of typhoid fever at Florence is now at an end, and that the condition of the water-supply is occupying the urgent attention of the local authorities.

**CESSATION OF CHOLERA IN ASIATIC TURKEY.**—The news received during the last of February by the sanitary authorities from the different provinces of the Turkish Empire was good. Cholera has totally disappeared. It is only by way of precaution that ships arriving at Beirut from the localities where previously cholera was raging, undergo a medical visit. In Constantinople besides small-pox, there is a little epidemic of mumps. The epizooty, which was raging near Trebizond, has totally disappeared.

**ASSOCIATION OF AMERICAN PHYSICIANS OF BERLIN.**—About forty American and Canadian physicians held a meeting on February 19th, at Berlin, in order to found a permanent organization such as exists in Paris, London, Edinburgh and Vienna. Professor Miller (University of Pennsylvania), now Professor at the University of Berlin, called especial attention to the fact that such an organization would not only greatly benefit the physicians who remain here for purposes of study, but also that it would call the attention of Germany to the forward tendency of American medical science. He strongly urged the publication of the transactions of the association every year. Permanent organization was effected, Dr. Judson Daland, of Philadelphia, being elected President, and Dr. F. Weber, of Milwaukee, Secretary. The objects and scope of the society, as set forth in the preamble, are: The arrangement of medical work and the formation of special private courses, so that any desired instruction may henceforth be obtainable at this University; the giving of advice to new-comers regarding instruction, lodgings, books, instruments, etc.; the reading and discussion of papers of general interest, exhibition of patients and demonstration of specimens in all lines of work taken up by members, the furthering of mutual ends by a more extended acquaintance of the physicians here. New-comers and others desiring information will please apply to the Secretary, Dr. Fred. R. Weber, Charité, Berlin.

#### BOSTON AND NEW ENGLAND.

**OPENING OF THE CARNEY HOSPITAL NEW BUILDING.**—The new main building of the Carney Hospital in South Boston was dedicated on April 1st, and opened to the public on April 1st and 2d. It is said that on the second day, being Fast Day, 20,000 persons visited the institution. By this addition, the capacity of the hospital is doubled, the number of beds being now about two hundred.

**COMMISSIONER OF PUBLIC INSTITUTIONS.**—The mayor of Boston has appointed Dr. Otis K. Newell to the Board of Commissioners of Public Institutions.

**A HOSPITAL FOR MALDEN, MASS.**—The trustees of the Malden Hospital Association have recently held a meeting to take steps towards the erection of a hospital in that city. It was voted to erect a building to cost about \$20,000. The Building Committee was authorized to perfect plans for the main building and to receive estimates thereon.

**AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF PHYSICAL EDUCATION.**—The sixth annual meeting of this association was held in Boston, April 3d and 4th, Dr. D. A. Sargent presiding. The papers read were as follows: "Is Physical Training a Trade or a Profession?" by the President; "Physical Education in Colleges," by Rev. W. D. Hyde, D.D.; "A Comparison of Measurements of Men and Women from our Colleges," by E. Hitchcock, M.D.; "The Growth of Children," by Prof. H. P. Bowditch, M.D.; "The Delsarte System of Æsthetic Exercises," by Mrs. Coleman Bishop; "Physical Education in the Young Men's Christian Association," by Luther Gulick, M.D.; "Athletics versus Gymnastics at Home and Abroad," by E. M. Hartwell, M.D.; "Physical Training in the Regular Army," by Charles R. Greenleaf, M.D., U. S. A.; "Some of Galton's Tests," by Kate C. Hurd, M.D.; "A System of Gymnastic Exercises for Public Schools," by Mr. Carl Betz; "The Muscular Strength of Growing Girls," by C. L. Scudder, M.D. At the business meeting Dr. E. M. Hartwell was elected president for the coming year. One hundred and sixty new members were elected. The next annual meeting of the association will be held in Baltimore. The following resolution was passed: "That a committee of five be chosen by this association to confer with the proper authorities and urge upon them the desirability and necessity for Congressional action in authorizing a professorship of physiology, hygiene and physical training at the United States Military Academy at West Point, and to take such other action in the premises as the committee may deem proper. The following were named as such committee: Dr. E. M. Hartwell, Dr. H. P. Bowditch, Dr. J. W. Sever, Dr. H. D. Wady and Dr. D. A. Sargent.

**INSURING INFANTS.**—The Insurance Committee of the Massachusetts Legislature on April 1st, gave a hearing upon the order as to regulating the placing of insurance by one person upon the life of another person, so as to prohibit the effecting of such insurance upon persons under specific age, and to prohibit such insurance upon a person who has no knowledge of it. No one appeared in favor of the order. It is reported that the counsel for one of the insurance companies, said that his company had built up a business in this line, insuring from two years of age and upward. He defined it as a "family insurance for burial purposes" so that upon the death of any one in the family a loss is paid from ten dollars up. The maximum is seldom

over one hundred dollars. The premiums range from five to fifty cents a week, but the latter is exceptional. The money is called for by the collector once a week. The business was established in England many years ago. The leading company in England has over one-fifth of the population of Great Britain and Ireland on its books. No proof has ever been given of the charge that children are murdered for the sake of getting insurance. The John Hancock Company and the Metropolitan Life of New York, are the only ones in this State which do this business. It is claimed that the business promotes economy and prevents debt. Limitations are carefully made on the lives of children. The average payment on children under thirteen is twenty-nine dollars. On adult lives the average payment is one hundred and two dollars. In this country no insurance is made on children under two years, though abroad they are insured as soon as they are born. The mortality of insured children is lower than the average among the population. In this country there are 3,750,000 policies in this branch of industrial insurance, thirty per cent. of which is upon lives under ten or twelve years. Commissioner Merrill thought it would be well to prevent the insurance of lives without the knowledge of the persons insured, if possible. The companies would be glad to see some way devised for this. He should recommend a law that companies should not set up the physical condition of the insured as a bar to claims where there was no medical examination. The Committee reported inexpedient to legislate.

#### NEW YORK.

THE BELLEVUE HOSPITAL MEDICAL COLLEGE Commencement was held in the large hall of the Carnegie Laboratory on Monday evening, March 30th. There were one hundred and fifty-two graduates, and the address to the class was made by Prof. A. A. Smith. A reception followed the exercises. On the evening following occurred the annual dinner of the Alumni Association of the College at the Hotel Marlborough.

THE MONTHLY BULLETIN OF THE STATE BOARD OF HEALTH shows that in February 8,701 deaths were reported in the State. Of this number New York City is credited with 3,026, and the maritime district entire with 5,930. The average total number of deaths for the past six years in February was 7,490, or 1,211 less than this year. The acute respiratory diseases were the cause of the greatest number of deaths of any one class, 1,683; which is 233 above the average of the past six years.

IMMIGRANTS RETURNED.—In conformance with the provisions of the new immigration law, which became operative April 1st, fifteen Italians suffering from phthisis and other diseases considered dangerous and infectious, which were brought over by the steamship *Infatigata*, were on April 3d sent to that vessel to be returned to the ports from which they came. The new law makes it mandatory on the steamship

companies' part to receive, maintain and return such immigrants as are rejected. The penalty for refusal is a fine of \$300, for every offence, and to enforce it it is provided that clearance papers shall not be granted to the vessel while such fine remains unpaid. Every immigrant, on landing at the Barge Office, is subjected to a strict medical examination by the physicians of the Immigration Bureau.

INFLUENZA.—On April 4th, Dr. John T. Nagle, Deputy Registrar of Records of Vital Statistics, made the following report in regard to the mortality of the city and the prevailing influenza: "The deaths in this city for the week ending April 4, 1891, were 1,100; the number for the week ending March 28th was 895; March 21st, 840; and March 14th, 813. The deaths in 1891 for the week ending March 14th, were 48 less, for the week ending March 21st, 23 less, for the week ending March 28th, 42 more, and for the week ending April 4th, 252 more than the average of the corresponding weeks of the past five years. The deaths from pneumonia for the last week were unusually high, 224, or an increase above the average of the corresponding week of the past five years of 110. The deaths from phthisis were 137, or 14 above the average, and the deaths from bronchitis were 60, or 9 above the average of the corresponding week of the past five years. Influenza and complications during the week were credited with 48 deaths, and during the preceding week with 10 deaths. Thirty-four of the deaths were stated to be from influenza combined with pneumonia, and six from influenza combined with bronchitis. The disease appears to have been much milder than the preceding epidemic, and I think it will fast disappear, judging from the mortality of the past few days, which was as follows: April 1st, 200; April 2d, 168; April 3d, 146; April 4th, 143. The death-rate last week was 34.39, and for the week previous, 28, while the average rate for the corresponding weeks since 1886 was 26.51.

#### Miscellaneous.

##### IMMUNITY FROM YELLOW FEVER.

DR. DOMINGO FREIRE, who was recently sent by the Brazilian Government to Berlin to study the Koch methods, described the bacteriological work done in connection with yellow fever, before the Verein für innere Medizin on March 9th. Yellow fever is due to the *Cryptococcus xanthogen*, a well-known organism. It produces two pigments, a yellow and a black, of which the former is soluble, and gives the characteristic color to the skin, the latter is not soluble, and is the cause of the black vomitus. The ptomaines contain a poison which acts on the medulla. In animals the disease can be produced by the ptomaines as well as by the pure cultures. Even by the third alternation of the culture, immunity can be produced. After protective inoculation, symptoms occur which resemble the initial stage of yellow fever, but disappear in forty-eight hours. The results between 1883 and 1890,

have been so favorable, that the Brazilian Government has recently founded an institute for the preventive inoculation of yellow fever, and authorized the expenditure of \$5,000 for bacteriological apparatus.

### MEDICAL INSPECTION OF IMMIGRANTS.

THE new immigration law, approved March 3, 1891, went into effect on the first of April. The law provides that all immigrants who are not admissible shall be returned by the steamship companies which brought them over. The following extracts from this law contain the provisions for medical inspection of new arrivals:<sup>1</sup>

*Be it enacted, etc.,* That the following classes of aliens shall be excluded from admission into the United States, in accordance with the existing acts regulating immigration, other than those concerning Chinese laborers: All idiots, insane persons, paupers or persons likely to become a public charge, persons suffering from a loathsome or a dangerous contagious disease, persons who have been convicted of a felony or other infamous crime or misdemeanor involving moral turpitude, polygamists, and also any person whose ticket or passage is paid for with the money of another or who is assisted by others to come, unless it is affirmatively and satisfactorily shown on special inquiry that such person does not belong to one of the foregoing excluded classes, or to the class of contract laborers excluded by the act of February twenty-sixth, eighteen hundred and eighty-five, but this section shall not be held to exclude persons living in the United States from sending for a relative or friend who is not of the excluded classes under such regulations as the Secretary of the Treasury may prescribe: *Provided,* That nothing in this act shall be construed to apply to or exclude persons convicted of a political offence, notwithstanding said political offense may be designated as a "felony, crime, infamous crime, or misdemeanor involving moral turpitude," by the laws of the land whence he came or by the court convicting.

SECT. 8. That upon the arrival by water at any place within the United States of any alien immigrants it shall be the duty of the commanding officer and the agents of the steam or sailing vessel by which they came to report the name, nationality, last residence, and destination of every such alien, before any of them are landed, to the proper inspection officers, who shall thereupon go or send competent assistants on board such vessel and there inspect all such aliens, or the inspection officers may order a temporary removal of such aliens for examination at a designated time and place, and then and there detain them until a thorough inspection is made. But such removal shall not be considered a landing during the pendency of such examination. The medical examination shall be made by surgeons of the Marine-Hospital Service. In cases where the services of a Marine-Hospital surgeon cannot be obtained without causing delay, the inspector may cause an alien to be examined by a civil surgeon, and the Secretary of Treasury shall fix the compensation for such examination. . . . That the Secretary of the Treasury may prescribe regulations for inspection along the borders of Canada, British Columbia and Mexico so as not to obstruct or unnecessarily delay, impede or annoy passengers in ordinary travel between said countries: *Provided,* That not exceeding one inspector shall be appointed for each customs district, and whose salary shall not exceed twelve hundred dollars per year.

### PRESCRIPTIONS.

**SALOL COLLOIDION.**—This application,<sup>2</sup> which is used in acute rheumatism, is prepared as follows:

R Salol { . . . . . aa 3 j.  
 (Etheria) {  
 Ft. solutio et adde  
 Colloidi . . . . . 3 j. M.

**VOMITING OF PREGNANCY.**—Struvers<sup>3</sup> recommends the following in the vomiting of pregnancy, and also in cases of acute gastralgia:

R Coeaine . . . . . gr. ij.  
 Antipyrin . . . . . gr. xxx.  
 Aquæ . . . . . 3 v. M.  
 Sig. A teaspoonful every one-half to one hour.

<sup>1</sup> Abstracts, Marine-Hospital Bureau.  
<sup>2</sup> Le Bulletin Médical, December 7, 1890.

### METEOROLOGICAL RECORD,

For the week ending March 28, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Signal Corps.														
Date.	Baro-	Thermo-	Relative		Direction		Velocity		We'th'r.		Rainfall in inches.

Medford	11,079	—	—	—	—	—	—	—	
Hyde Park	10,193	—	—	—	—	—	—	—	
Peabody	10,158	—	—	—	—	—	—	—	

Deaths reported 2,960; under five years of age 1,010; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers) 329, acute lung diseases 862, consumption 308, diphtheria and croup 82, scarlet fever 61, diarrhœal diseases 42, measles 41, typhoid fever 34, cerebro-spinal meningitis 30, whooping-cough 22, erysipelas 11, malarial fever 6.

From measles New York 12, Brooklyn 10, Washington 7, Chicago 6, Boston and Nashville 2 each, Springfield 1. From typhoid fever Chicago 16, Washington 6, New York and Lawrence 3 each, Cincinnati 2, Charleston, Lowell and Springfield 1 each. From cerebro-spinal meningitis Chicago 15, New York 7, Brooklyn and Washington 2 each, Nashville, Salem, Malden and Fitchburg 1 each. From whooping-cough New York 11, Brooklyn 6, Chicago and Washington 2 each, Charleston 1. From erysipelas New York 6, Chicago 3, Washington 2. From malarial fever New York and Brooklyn 3 each.

In the twenty-eight greater towns of England and Wales with an estimated population of 9,715,559, for the week ending March 21st, the death-rate was 21.9. Deaths reported 4,198; acute diseases of the respiratory organs (London) 556, measles 181, whooping-cough 117, diphtheria 52, fever 39, diarrhoea 38, scarlet fever 22.

The death-rates ranged from 12.6 in Derby to 36.0 in Blackburn, Birmingham 19.6, Hull 20.9, Leeds 24.6, Leicester 20.4, Liverpool 22.5, London 20.3, Manchester 28.1, Nottingham 17.4, Sheffield 20.3.

In Edinburgh 23.1, Glasgow 22.8, Dublin 28.4.

#### OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MARCH 28, 1890, TO APRIL 3, 1891.

The leave of absence for seven days granted Captain J. VAN R. HOFF, assistant surgeon, in Orders No. 61 (c. s.), Fort Riley, Kan., is extended twenty-three days. S. O. 36, Par. 3, Department of the Missouri, March 27, 1891.

By direction of the Acting Secretary of War, Major JOSEPH B. GILKARD, surgeon, is relieved from duty at Fort Lowell, Arizona, to take effect upon the withdrawal of the troops from that post, and will report in person to the commanding officer, Alcatraz Island, Cal., for duty at that station, reporting by letter to the commanding general, Department of California. S. O. 70, Par. 5, Headquarters of the Army, A. G. O., Washington, March 28, 1891.

Captain HENRY G. BERTON, assistant surgeon, now at San Diego, Cal., on sick leave of absence, is relieved from further duty at Vancouver Barracks, Wash., and will report in person to the commanding officer, San Diego Barracks, Cal., for duty at that post, relieving Major DAVID L. HUNTINGTON, surgeon, and reporting by letter to the commanding general, Department of Arizona. S. O. 71, Par. 5, Headquarters of the Army, A. G. O., March 30, 1891.

Major DAVID F. HUNTINGTON, surgeon, on being relieved by Captain HENRY G. BERTON, assistant surgeon, from duty at San Diego Barracks, Cal., will report in person to the commanding officer, St. Francis Barracks, St. Augustine, Fla., for duty at that post, reporting by letter to the commanding general, Division of the Atlantic. S. O. 71, Par. 5, Headquarters of the Army, A. G. O., March 30, 1891.

By direction of the President the following-named officers are detailed for duty under the Intercontinental Railway Commission, appointed under a provision in the Act of Congress approved July 14, 1890, for the purpose of making "a preliminary survey for information in respect of a continental railway recommended by the International American Conference," and they will report in person to the Commission in this city accordingly: Captain EDGAR Z. STEWART, Third Cavalry; First Lieutenant STEPHEN M. FOOTE, Fourth Artillery; First Lieutenant LYMAN W. V. KENNON, Sixth Cavalry; First Lieutenant ANDREW S. ROWAN, Ninth Infantry; Second Lieutenant SAMUEL BLISS, Fourth Cavalry; Second Lieutenant CHARLES A. HEIDEN, Third Cavalry; Captain WILLIAM C. SHANNON, assistant surgeon U. S. A., for duty as medical officer of the party to which he may be attached. S. O. 73, Par. 9, Headquarters of the Army, A. G. O., Washington, April 1, 1891.

#### OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING APRIL 1, 1891.

F. R. STEPHENSON, surgeon, ordered to the U. S. S. "Macon."

T. B. BERRYHILL, passed assistant surgeon, ordered to the U. S. S. "Macon."

C. H. WHITE, medical inspector, ordered to the U. S. S. "Baltimore."

J. H. CLARK, medical inspector, ordered to the U. S. S. "San Francisco."

A. A. HOBBS, medical inspector, detached from President of Naval Examining Board.

REYNOLD C. CRANDALL, assistant surgeon, promoted to passed assistant surgeon, February 27, 1891.

CAPT. DE WOLF BROWNELL, of Bristol, R. I., commissioned as assistant surgeon in the Navy, April 1st.

#### SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. A regular meeting of the Society will be held on Monday, April 13, 1891, at the Medical Library, 10 Boylston Place, at 8 o'clock P. M.

REPORTS BY H. A. BEACH, "Compression in the Treatment of Aneurysms," Dr. W. F. WHITNEY, "The Pathological

Anatomy of the Appendix Cæci, with Especial Reference to Acute and Chronic Appendicitis, with Lantern Illustrations." Election of new members, meeting at 9 o'clock.

G. G. SEARS, M.D., Secretary.

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.—The meetings of the Congress of American Physicians and Surgeons will be held in Washington, from 3 to 6 P. M., September 22, 23, 24 and 25, 1891.

WILLIAM PEPPER, Chairman of the Executive Committee.

#### ERRATUM.

In the report of the meeting of the Johns Hopkins Hospital Medical Society, published in the last issue of the JOURNAL, many unfortunate errors appear. The quotation attributed to Ehrlich is incorrect. Readers interested in the report of the proceedings of this meeting will find a full report in the next issue of the *Johns Hopkins Medical Bulletin*.

#### OBITUARY. CHARLES T. PARKES, M.D.

Dr. Charles T. Parkes, one of the best known surgeons of Chicago died, March 28th, of pneumonia, aged forty-eight. Dr. Parkes was born in Michigan, and graduated from the Rush Medical College. In 1868 he became demonstrator of anatomy in that institution, in 1875 he was made professor, and in 1885 became professor of surgery. He was also surgeon to the Presbyterian Hospital, treasurer of the Rush Medical College, and president of the Chicago Medical Society. His sudden death, coming just at the commencement season, cast a gloom over the graduating exercises of the largest class in the history of the Rush Medical College.

#### OBITUARY. JOHN P. GARRISH, M.D.

Dr. John P. Garrish, one of the oldest and best known New York physicians, died April 1st. He graduated from Jefferson Medical College in 1836, and afterwards practised for a time in that city. In 1840 he removed to New York. During his fifty years' experience he probably attended more midwifery cases than almost any physician who ever resided there. He also devoted much attention to diseases of the eye and ear. Dr. Garrish was always much interested in medical societies, and was one of the founders of the New York Academy of Medicine and of the New York County and State Medical Associations.

#### OBITUARY. JAMES BATHGATE, M.D.

Dr. James Bathgate died in New York March 27th. He was born in 1825, and received his collegiate education at the University of the City of New York. He afterwards studied medicine with the late Prof. Joseph Mather Smith, and graduated from the College of Physicians and Surgeons, New York, in 1847. For some years he was attached to the New York Hospital and the New York Dispensary, and afterwards removed to the family homestead at Morrisania, where he continued to reside up to the time of his death.

#### DEATHS.

FRANK J. WEED, M.D., of Cleveland, O., Dean of the Wooster University Medical College, died, March 27th, aged forty-six.

HARVEY S. GAY, M.D., of New York City, died, March 25th, aged sixty-five.

THOMAS B. REED, M.D., Surgeon to the Presbyterian Hospital, etc., died in Philadelphia, April 1st, aged fifty-six.

RICHARD G. H. BUTCHER, M.D., F.R.C.S.L, died in Dublin, March 21st, aged seventy-two. He was the inventor of a surgical saw called by his name, and of other apparatus.

EUGEN JENDRASSIK, M.D., the distinguished Professor of Physiology in the University of Budapest, aged sixty-seven.

KARL BLOHM, M.D., Emeritus Professor of Ophthalmology in the University of Graz, aged seventy-four.

#### BOOKS AND PAMPHLETS RECEIVED.

Psoriasisformis Follicularis Cutis. By L. Duncan Bulkley, A.M., M.D., Professor of Dermatology. Reprint. 1890.

What is the Essential Basis of Professional Ethics, and the Proper Relation of Trade? By J. Morgan Howe, M.D., M.D.S. Reprint. 1890.

THE ANTI-BAR LAW. The Twenty-five-Foot Law. Argument of Louis D. Brandeis, Esq., before the Joint Committee on Liquor Law, of the Massachusetts Legislature. Boston, February 27, 1891.

## Original Articles.

## IS THE STUDY OF MEDICINE A LIBERAL EDUCATION?

BY DAVID W. CHEEVER, A.B., M.D.

Among the Greeks, a temple was built and dedicated to Hippocrates; and in the Middle Ages, Ambrose Paré, was welcomed in a besieged city, as equal to a strong reinforcement by troops. But in modern times the pseudo-sciences and the various "patlies" have thrown discredit on medicine, while the admitted uncertainties of the art, have belittled the advances in the science of healing. It is, however, precisely here that we are justified in showing, the sharp contrast, with the modes of learning even fifty years ago; in claiming that medicine, as now studied, is a liberal education; and that a well-equipped medical school is equal to other institutions of learning.

The times have changed, and we with them, since the days of Dr. Samuel Johnson, when, he defined in his dictionary the humanities, as philology, grammatical studies, *humaniores literæ*. Few would now claim for a purely classical education the name of a liberal one, to the exclusion of the study of the natural sciences. The immense debt of civilization to modern advances in technology, the adaptation of new laws and new forces in nature to our daily use and our daily needs, properly assert the right of purely scientific pursuits to be reckoned the equal of the humanities, which formerly were represented only by languages and literature. Yet modern medical study includes both the languages and science. Latin is interwoven with anatomy too intimately to be disentangled. Botany and pharmacy equally require a fair acquaintance with this ancient tongue. Greek is more used in scientific nomenclature, and above all in the specialties of medicine, than in modern literature. German is indispensable to modern medical investigation; and so also is French. Ancient and modern languages, then, four in number, besides the vernacular, are required elements in a medical education to-day. In this respect the medical school is closely allied to the purely classical college. But even without this, we may justly claim that medicine, as now studied, requires an intimate knowledge of science, and also that the doctor, next to the naturalist, has the cultivation of his powers of observation carried higher than in any other profession. The *vezatio nature* of Bacon, the test of experiment, the clinical observation of disease, develop the highest faculties, and are a liberal education.

The study of medicine is wholly by *observation*. The practice (or art) of medicine is the result of *experiments*. Medical science is then strictly *inductive*. Theories of medicine may lead to *deductions*, often to false ones.

Let us attempt to define the terms observation, experiment, induction, deduction.

Observation: What we learn by using our senses — looking, hearing, touching, observing.

Experiment: The trial of anything, something done to discover an unknown effect.

Induction: To generalize from observation and experiment.

Deduction: A consequence from principles premises.

For example: Watt *observed* that boiling water turned to steam, that steam lifted the cover of a kettle;

he *experimented* to see if it would move other objects; by *induction* he generalized the law of the expansion of steam. Theologians premise that God oversees the world; they *deduce* from this premise the principles of religion.

Says Mr. Buckle: "Science is the result of inquiry; theology is the result of faith. In the one, the spirit of doubt; in the other, the spirit of belief. In science, originality is the parent of discovery, and is therefore a merit; in theology, it is the parent of heresy, and therefore a crime. . . . The popular tendency of induction is obvious: for one person who can think, there are a hundred who can observe. . . . Facts seem to come home to every one, and are undeniable. Principles are not so obvious; and being often disputed, they have, to those who do not grasp them, an unreal and illusory appearance, which weakens their influence. Hence it is that inductive science, which always gives the first place to facts, is essentially popular, and has on its side those innumerable persons who will not listen to the more refined and subtle teaching of deductive science. Hence, too, we find historically, that the establishment of the modern inductive philosophy, with its varied and attractive experiments, its material appliances, and its constant appeal to the senses, has been intimately connected with the awakening of the public mind, and coincides with that spirit of inquiry, and with that love of liberty, which have been constantly advancing since the sixteenth century."

The novel, recent and enlarging use of instruments of precision, together with the progress in physiology and microscopy, have been the great factors in changing the whole scope of medical instruction. To summarize briefly what the medical student is supposed to learn in a four years' course, will make this plain.

The required course of the Harvard Medical School covered in 1870 about four months in each of three years, the same public lectures being repeated every year, so that the student could not follow a properly graded course; the required course of the same school now covers nine months in each of three years, and the instruction is different in each year of the student's course. In addition, a voluntary fourth-years' course is maintained, and a great variety of instruction for graduates is given. All candidates for admission, except those who have passed an examination for admission to Harvard College, must present a degree in letters, science, or medicine, from a recognized college or scientific school, or pass an examination in the following subjects: —

(1) English. Every candidate will be required to write, legibly and correctly, an original English composition of not less than two hundred words, and also to write English prose from dictation.

(2) Latin. The translation of easy Latin prose.

(3) Physics. A competent knowledge of Physics (such as may be obtained from Balfour Stewart's "Elements of Physics").

(4) Elective Subject. — Each candidate must pass an examination in any one of the following subjects: French, German, the Elements of Algebra or of Plane Geometry, Botany.

## DIVISION OF STUDIES. FOUR YEARS' COURSE.

For the First Year. — Anatomy, Physiology, General Chemistry, Medical Chemistry and Materia Medica.

For the Second Year. — Practical and Topographical Anatomy, Medical Chemistry, Pathological Anatomy, Clinical Medicine, Surgery, Clinical Surgery, Therapeutics and Diseases of Children.

For the Third Year. — Obstetrics, Theory and Practice of Medicine, Clinical Medicine, Surgery and Clinical Surgery.

For the Fourth Year. — Ophthalmology, Otology, Dermatology, Laryngology, Mental Diseases, Diseases of the Nervous System, Gynecology, Diseases of Children, Legal Medicine, Orthopedic Surgery, Genito-urinary Diseases, Hygiene, Vacci-

nation, Bacteriology, Ovarian Tumors, Clinical Microscopy and the Preparation of Food for Infants and Invalids.

This course may be passed in three years, provided certain of the special studies of the fourth year are taken as electives.

To learn medicine, we begin to study: (1) chemistry, or the composition of inorganic and organic bodies; (2) the dead man, healthy—or anatomy; (3) the dead man, sick—pathology; (4) the living man, healthy—physiology; (5) the living man, sick—clinical medicine. Many collateral sciences are also studied, as physics, botany and others.

Chemistry has revolutionized the arts of living; and it has equally revolutionized the practice of medicine. Bulky, inert or incompatible drugs have been resolved into the potent alkaloid, which is both cleanly and palatable. The chemical changes undergone by remedies in the complex laboratory of the human body have also been carefully studied. The fluids of the body have been analyzed. General chemistry and medical chemistry require long courses of months spent in the laboratory, before the student is permitted to advance to other branches.

Anatomy, that fascinating study of the structure, and complex machinery of life, is studied on the dead body. No pursuit is more ennobling; none reveals more plainly the exquisite mechanics of living structures and the design of our Creator. So long, so labored, so minute have been dissections, that it has been said that anatomy was learned out, and there could be nothing new to discover. So far from this being true, the microscope has taken up and prolonged our search; and histology, or the study of tissues and cells, has opened up a new world of investigation. Anatomy is studied in our medical school, one entire year, half a second year, and there is a daily exercise in it for three and four years.

Pathology is anatomy altered by disease. While descriptive anatomy, or macroscopy, is now supplemented by microscopy; the gross outlines of the sculptor, by insight into the minutest tissues, so in pathology, this insight penetrates the deepest crypts of disease, maps out growths, describes cell-arrangement, and in bacteriology pursues the parasitic germ to its home in the tissues and describes its habits and its *habitat*. Creative cellular forces are traced back in embryology to the protoplasm, and the primal cleft.

From anatomy and pathology grows surgery. And who can measure the future of modern surgery, except by contrast with its vast advance in the last twenty years? The germ theory of disease and the use of germicides or antiseptics have changed suppurations to painless healings, banished many *opprobria* and failures of operations; and, together with anesthesia, have rendered the surgeon bold, accurate and safe in many novel operations on the abdomen, the viscera, and the brain. The surgical field thus enlarged; the focus of surgical observation brought down to infinitesimal minuteness; counting blood globules; estimating white cells; resolving bacilli,—all this has to be learned, and learned by observation and practice, in a modern medical education.

Physiology, the science of nature, or of life rather than the knowledge of function, of use, of habit; in health, in disease—has also been developed almost as far as the knowledge of physics has been enlarged in physical laboratories. Experiment is the path of physiology; along this path she moves steadily upward;

and by experiments on lower animals, medical practice is most rapidly advanced. No one unfamiliar with it can realize the extent of the appliances and details of a modern physiological laboratory. Here, then, the medical student has a vast field of study.

Just as the great artist must study and copy the human face and form as his most difficult lesson, if he would excel in any department of painting, so man offers to the medical observer the most complex and least scrutable problem. He lives, grows, decays, revives, assimilates, excretes, gains, wastes,—all at the same time. Cells travel, reside, procreate, develop, decay, form healthy or diseased tissues, side by side. Chemical interchanges, vital forces, nervous influences, all combine in life. Mental processes influence bodily ones; and all these are to be weighed, counted, balanced, measured, in estimating the health or the sickness of the individual. The trained eye, the educated ear, the erudite touch, must all be guided by prolonged clinical experience, to constitute the medical observer the true physician. It is in our great hospitals and dispensaries that this highest educing of the faculties must be practised by the medical student.

Modern science has offered to the observer numerous instruments of precision to guide his observation. The clinical thermometer is the safety-dial of diagnosis. The stethoscope magnifies the sounds of the heart and lungs, and makes plain slight vibrations otherwise inaudible or unnoticed. The ophthalmoscope illuminates the bottom of the eye and the retina. The laryngoscope reveals the vocal chords; the endoscope numerous cavities, which are also made visible by the electric light. The microscope extends the natural eye of the observer to the cellular basis of all the tissues. Synthetic chemistry compounds the excreta of bacilli to arrest the progress of the germs themselves.

If we add to all this the tendency in medicine, as in all pursuits, to specialize, we may realize how every field must be magnified by minute research.

Besides, medical studies form close partnerships with the law, in medico-legal questions, and in sifting crimes. The analysis of poisons, the recognition of blood, the determination of the time and the cause of death, the weighing of accountability, the estimation of mental competency,—all are settled by the medical expert.

In the noblest field of all, preventive medicine in hygiene modern medical education is making the greatest progress. To cleanse milk of tubercle bacilli, to detect filaræ, to dispose safely of drainage, to purify water, are the pressing scientific as well as practical problems always testing the knowledge and the keenness of the medical observer.

Just as colleges, as they broaden, aspire to give advanced instruction, so, also, the medical school is providing post-graduate and advanced courses for original research, and for specialized study.

The treatment of disease has always been considered the highest attribute of the physician. In this department all his previously acquired knowledge is grouped, classified, utilized. No vaunted specific is left untried; the earth is ransacked for remedies; and they are all tested by experiment.

Can we deny, then, to the study of medicine its place among the noble sisterhood of the sciences of civilization? Her present methods no more resemble older ones, than the steamship or the electric light of to-day, resemble the galleys of the Roman or the

*lucerna* of Pompeii. What can be a more liberal education than drawing out the faculties of observation, learning by experience, comparing and generalizing by induction, as we do in the medical school; but demanding, as a prerequisite, a knowledge of English, of Latin, of physics, either German or French, and some mathematics; and considering, as best of all, a preliminary mixed classical and scientific academic course and degree?

To accomplish all this, to preserve health and youth, to render it within the means of parents and boys to get a complete medical education, it is essential that the doctor should not start in the race of life too heavily weighted by years. What are the present facts? How early, or how late rather, can a sound academic and professional education be attained?

"As matters now stand, one-half of the students who enter Harvard College—that half, namely, who become ministers, lawyers, or physicians—enter, on the average, at nineteen, take the degree of Bachelor of Arts at twenty-two and three-quarters, and complete their training for the learned professions at twenty-five and three-quarters or twenty-six and three-quarters years. In the opinion of the majority of the Faculty these ages are all unreasonably high."<sup>1</sup>

Seven or eight years are now required to get an A.B. and an M.D. degree. Both are valuable. Can they not be combined? The plan proposed by the Harvard Medical School, was to have the scientific and elementary medical studies, as chemistry, anatomy, physiology, and perhaps botany, made electives for the senior year at Cambridge; so that the junior who had decided on medicine as his life-pursuit, could select in his last or senior year at Cambridge, studies which led him directly to his profession. Three years in the Medical School would then count as four, and he would graduate an M.D., one year younger than by the present method. This method, when reduced to its simplest terms, consists in counting certain agreed-upon courses of professional instruction both for the degree of Bachelor of Arts and for the professional degree.

In the words of the majority report of the Faculty: "They can find no warrant in the educational history of older nations for the American practice of holding the best educated young men back from professional study until they are twenty-three years of age, or more. Thus, at Oxford and Cambridge, professional studies may be counted to a large extent for the A.B.; the German youth leaves the gymnasium at from nineteen to twenty years of age on the average, and at once is free to begin in the university his preparation for some learned profession; the French boy is even younger when he chooses a career and begins professional study."

The Edinburgh University has just lengthened its medical curriculum to five years; but the average age of the matriculating medical student is nineteen years. It is a singular anomaly that in America the well-educated doctor must start later in the competition race for a living, than in other communities.

The objections made in the report of the majority of the College Faculty are fallacious. They are practically these: that this proposed method "abolishes the fundamental distinction between liberal and professional studies, . . . confounds all distinction between pure and applied science." What are liberal studies? Must we confine ourselves to-day to the *humaniores literæ*?

<sup>1</sup> Report of a majority of the Faculty of Harvard College.

Is induction liberal? Shall we go back to the period of learning before Bacon? What is pure science? Is chemistry pure, as well as applied? Are not anatomy and physiology as liberal as geology, physical geography, zoology, physics?

#### EXCISION OF THE ELBOW-JOINT: ULTIMATE RESULTS AT THE MASSACHUSETTS GENERAL HOSPITAL, BOSTON, MASS.

COMPILED BY CHARLES L. SUDDER, M.D.,  
Assistant in Clinical Surgery, Harvard University.

At the Massachusetts General Hospital, Boston, Mass., there were performed, from May 23, 1822, to September 25, 1887, ninety-five excisions of the elbow-joint; including both partial and complete operations, for ankylosis from various causes, for caries of one or more of the joint surfaces, and for compound fracture.

Dr. Richard M. Hodges, in his book on "Excision of the Joints," published in 1861, recorded all cases in literature to that date.

Dr. H. H. A. Beach, in the *Boston Medical and Surgical Journal* for January 4, 1877, reported cases occurring at the Massachusetts General Hospital for ten years previous to 1877, in the service of Dr. R. M. Hodges. Dr. Culbertson, in the Prize Essay of the American Medical Association for 1876, has collected all cases from all nations to that date, including those of Dr. Hodges.

The cases reported here in detail, and grouped in Tables I, II, and III, include only those from whom ultimate results are known, of all treated at the hospital during the ten years immediately preceding 1887.

The total number operated on during these ten years is 36. Of these, 16 reported, seven in person and nine by letter, in response to questions. These 16 cases of excision of the elbow-joint are reported in order to record the results after this not uncommon operation. In all cases the method of excision was by the long single incision over the olecranon and posterior surface of the humerus. The after-treatment was by "antiseptic dressing," and usually an internal angular splint. Drainage-tubes of rubber, sutures of silk, and ligatures of catgut were used.

Of the four cases excised for ankylosis two became again ankylosed. Each of these cases had some motion upon leaving the hospital. These two failures were probably due to the non-maintenance of passive motion after operation, together with the removal of too little bone or the leaving of too much periosteum.

Of the four cases excised for compound fracture of the joint, one died of septicaemia.

In this connection it is of value to note that of all the cases with penetrating wounds of the joints, brought into the accident-room of the hospital, those do poorly and are most liable to septicaemia which have remained many hours away from the hospital after the receipt of the injury (see Case VI).

The first treatment of one of these injuries is of the greatest importance, not only to the wounded part itself, but to the life of the individual. It should be generally recognized that every recently injured elbow, before being sent to the hospital, demands careful cleansing, and at least, the cleanest possible dressing procurable, when antiseptic materials are wanting.

As a rule, after excision for injury, the wounds heal quickly, and the end result is a useful joint.

After excision for diseased bone the result is good. Case I died of general tuberculosis so long after excision that it cannot be considered a factor in causing death.

The influence of operative interference in tuberculous joints on the dissemination of the disease has not yet been fully determined.

The most recent facts bearing on this point are published by König, who observed 16 cases of miliary tuberculosis following shortly after resection of tuberculous joints; and by Wartmann,<sup>1</sup> who has collected from the practice of different operators 837 cases of excision for tuberculosis, of which 225 died, and of these fatal cases 26 followed the operation closely, and were due to miliary tuberculosis.

To avoid the introduction of bacilli or tuberculous bits of tissue into the systemic circulation through the opened veins of the wound, it seems necessary to remove very carefully all the diseased part, including all the synovial and peri-articular tissues that may be involved, and before removing the tourniquet to thoroughly disinfect the wound with bichloride of mercury (1 to 1000).

In almost all cases excised for disease, after leaving the hospital there was a slight discharge from a small sinus at the seat of operation for a few weeks or months.

It is an interesting fact that the time of treatment and stay in the hospital for all cases during the past ten years, is much less than that necessary before that time. This is probably due to the more thorough operation of to-day, and the advantages of a better wound treatment.

Following are the reported cases, grouped under the three headings:

- Excision for ankylosis.
- Excision for compound fracture.
- Excision for diseased bone.

These questions were addressed to the cases of excision occurring during the past ten years:

1. What work can you do with the arm?
2. Is there any stiffness of the fingers?
3. Can you touch the back of neck with hand?
4. Can you straighten arm?
5. What weight can you lift from the side up to the shoulder?
6. How strong a blow can you strike from the shoulder?
7. Has the discharge of matter from the elbow ceased? If so, when did it cease?
8. Has the elbow ever given you any trouble?

TABLE I — Cases Excised because of Ankylosis of the Elbow-Joint.

No.	Sex	Age	Disease.	Time before operation.	Treated	End of	Condition.
1	M.	6	Dislocation of elbow	8 mos.	8 wks.	6 yrs.	Very useful
	M.	..	Abscesses about joint	5 mos.	8 wks.	5 yrs.	Fair, ankylosis at obtuse angle
	M.	10	Obescurum in art.	6 mos.	12 wks.	3 yrs.	Fair, ankylosis at obtuse angle
1	F.	10	Obescurum in art.	1 mos.	3 wks.	11 mos.	Very useful

<sup>1</sup>Deutsche Zeitschrift f. Chirurgie, B. xxiv, Heft 5, 6.

CASE I. Operator, Dr. R. M. Hodges. Ankylosis of the elbow. Excision. Recovery. Vol. cc, p. 164.

Boy, aged six, said to have dislocated his elbow some eight months previous to entrance to hospital. Elbow was immovable. Abscess near joint. Joint exposed. Elbow was excised by the usual method. At the end of eight weeks discharged, with some motion. Wounds all healed.

At the end of six years. Can do anything and everything with the arm. No stiffness of the hand or fingers. Rotation is good. Can touch back of neck with hand. Cannot quite straighten arm in complete extension. Flexion is perfect. Can lift eight pounds from side to above shoulder. Never any discharge of matter since left the hospital.

CASE II. Operator, Dr. J. C. Warren. Ankylosis of the elbow. Excision. Recovery. Vol. ccii, p. 141.

Man, aged thirty-five. For some five months before entrance to hospital elbow was stiff, following abscesses about the joint. Arm is atrophied and elbow is ankylosed at an obtuse angle. Elbow excised by the usual method. No abscesses. Some motion at the end of eight weeks.

After five years writes that, "I can do anything which does not require very much strength. No stiffness of the fingers. I cannot bend the arm at all. Arm is at an angle of about 120 degrees. Cannot strike at all from the shoulder. Discharge ceased three months after discharged from the hospital. In cold or changeable weather arm troubles me."

CASE III. Operator, Dr. C. B. Porter. Ankylosis of the elbow. Excision. Recovery. Vol. ccxxii, p. 52.

Boy, aged ten, sustained an obscure injury to elbow some six months previous to entrance to hospital, which resulted in complete ankylosis yielding to passive motion under ether. Excision of the joint done by the usual method. Joint became stiff and was moved passively under ether. After twelve weeks was discharged, with considerable motion.

Three years after operation. Arm firmly ankylosed at an obtuse angle. Can touch back of head with hand. Rotation good. Fingers all right. Does considerable work, splitting wood, etc., at home. No abscesses since left the hospital. Is still rather thin and puny, but is growing fast.

CASE IV. Operator, Dr. A. T. Cabot. Old injury to elbow. Ankylosis. Excision. Recovery. Vol. ccxxiii, p. 89.

Woman, aged forty-eight, sustained an obscure injury to the elbow-joint, which resulted in complete ankylosis. Excision of the joint was done by the usual method, and in three weeks and a half after the operation, the patient was discharged, with all wounds healed and a little motion at elbow. Upon opening the joint the coronoid process of the ulna and the head of the radius were found fractured, and both radius and ulna dislocated backward. An attempt, before excision, was made to reduce the dislocated elbow, under ether, but in vain. Very little passive motion was possible.

Five months after operation. "I can do various kinds of work about the house. Sweeping is the hardest thing I can do. My fingers are stiff in the morning and the first joint has been stiff ever since my arm was hurt. I can touch the back of my neck and a little below neck with hand. I can dress my hair the past month. I can straighten my arm. My

arm isn't very strong but it is of more use than before the operation. There has been no discharge since I left the hospital."

Eleven months afterward. "I can do about any kind of work, of course my arm tires easily, still, think it is gradually gaining, and I find no inconvenience in readily putting it to my head, back of neck, or any place thereabouts. Can lift nothing to my shoulder heavier than a large book."

TABLE II.—Cases Excised because of Severe Compound Fracture into the Elbow Joint.

Case.	Sex.	Age.	Disease.	Time before operation.	Treated	End of.	Condition.
5	F.	42	Compound fracture (crush)	Several hours	6 days	....	Died, septicæmia
6	M.	21	Compound fracture (crush)	4 wks.	11 wks.	6 mos.	Very useful
7	M.	23	Compound fracture (fall)	Few hours	9 wks.	4 yrs.	Fairly useful
8	M.	37	Compound fracture (crush)	24 hrs.	6 wks.	6 mos.	Fairly useful, partial ankylosis at obtuse angle

CASE V. Operator, Dr. H. J. Bigelow. Compound comminuted fracture of the elbow. Excised. Death on the sixth day. Septicæmia. Vol. CLXXX, p. 26.

A woman, aged forty-two, had the right elbow caught in the roller of a printing press. Before coming to the hospital several pieces of bone were removed and the arm put into an internal angular splint. Upon entrance, the region of the right elbow was much swollen and ecchymosed, and a lacerated wound appeared over the internal condyle of the humerus. The joint was excised by a straight incision over olecranon process of the ulnar. Radius intact, tip of olecranon fractured, coronoid process of the ulnar fractured. The joint capsule was found open. Lister dressing and carbolic poultices were applied. Arm on a pillow.

Death on the sixth day, from septicæmia.

CASE VI. Operator, Dr. H. J. Bigelow. Compound fracture of the external condyle into the joint. Partial excision. Recovery. Vol. CXC, p. 52.

A man, aged twenty-one, had elbow jammed between two railroad cars. Upon entrance to the hospital the external condyle and the head of the radius were found fractured. After four weeks, with no improvement from rest and local applications, the end of the ulnar and the external condyle of the humerus were removed. Lister dressing applied. Arm placed on a pillow. Discharged at the end of eleven weeks, all wounds healed. Fair amount of motion in fingers and elbow.

At the end of six months patient was seen, and found to be able to do almost as much with the injured arm as with the well one.

CASE VII. Operator, Dr. H. J. Bigelow. Compound dislocation and fracture of both bones of the forearm at elbow-joint. Excision. Recovery. Vol. CCXI, p. 279.

Man, aged twenty-three years, fell twenty-eight feet from a roof, striking on elbow. Radius broken obliquely, between the tuberosity and the head. The tip of the coronoid process was broken off. Little

finger could pass easily below internal condyle, into the elbow-joint. Joint excised. Lister dressing. Abscesses formed around the elbow. Discharged after nine weeks with fair amount of motion in elbow and small granulating wound.

Four years after the operation. Rotation perfect. Flexion good. Power of extension slight. Pain in wet weather. Four months after discharge wound broke out, and some pieces of dead bone removed. Again, two years after discharge, more dead bone removed. No stiffness of hand or fingers. All ordinary work can be done. Can touch back of neck with hand easily.

CASE VIII. Operator, Dr. M. H. Richardson. Compound fracture of elbow-joint. Excision. Recovery. Vol. CCXXXII, p. 237.

Man, aged thirty-seven, had arm run over by horse-car. One day later entered hospital. Internal condyle fractured, an opening on either side of the joint into the joint, flexion and extension good, rotation good. Excision done by the usual method. Arm very much swollen and tense. At the end of six weeks was discharged. Some motion in elbow. Small granulating surface over elbow. Man refused to attempt motion in arm.

Half a year after discharge. Elbow partially ankylosed at an obtuse angle. A few degrees of motion in flexion and extension possible. No pain in arm. Rotation absent. Cannot touch back of head with hand. Does considerable work with arm. Fingers a little stiff yet. Saws and splits wood easily. Wound healed solidly.

TABLE III.—Cases Excised because of Caries of the Bones of the Elbow Joint.

Case.	Sex.	Age.	Disease.	Time before operation.	Treated	End of.	Condition.
9	M.	19	Caries	4 mos.	14 mos.	3 yrs.	Died, general tuberculosis.
10	M.	54	Caries	15 yrs.	12 wks.	9 yrs.	Very useful
11	F.	11	Caries	6 mos.	25 wks.	8 yrs.	Fairly useful
12	F.	25	Caries	10 mos.	12 wks.	7 yrs.	Very useful
13	F.	18	Caries	9 mos.	16 wks.	4 yrs.	Very useful
14	F.	14	Caries	9 mos.	4 wks.	4 yrs.	Very useful
15	M.	19	Caries	2 yrs.	5 wks.	1 yr.	Fairly useful
16	M.	12	Caries	1 mo.	8 wks.	1 yr.	Useful

CASE IX. Operator, Dr. R. M. Hodges. Caries of elbow. Excision. Recovery. Vol. CLXXXI, p. 5.

Boy, aged nineteen years, delicate and anæmic, has a swollen elbow, presenting many sinuses connecting with the joint. The duration of the disease is about four months. Elbow excised by the usual method, and a cold water dressing applied. At the end of fourteen months, patient discharged with sinuses about the joint. No use of the arm.

This patient had abscesses in other parts of the body, apparently connecting with diseased bone. Abscesses formed about the elbow-joint, and required opening.

This patient died of general tuberculosis in 1882, about three years after leaving the hospital. The ulcers never healed. Could do none but the lightest work with arm. The stiffness of the fingers that existed when he was in the hospital never entirely disap-

TABLE IV.—Cases Excised because of Caries of the Elbow-Joint.

No.	Name.	Age.	Sex.	Where done.	Disease.	Duration.	Condition.	Operation.	Immediate Result.	Year.
1	G. C. C.	41	M.	M. G. Hosp.	Caries.	3 mos.	Sinus, swelling, stiffness.	Complete excision		
2	M. H. D.	45	F.	M. G. H.	Caries.	8 mos.	Sinus, swelling.	Complete excision	Death, septicaemia, in 6 days.	1876
3	M. D.	14	F.	M. G. H.	Caries.	1½ years.	Swelling, anteriorly and posteriorly.	Complete excision (pus in joint)	Recovery, 5 weeks, granulating wound, no splint.	1869

13	C.	19	F.	M. G. H.	Caries.	14 mos.	Swelling, stiffness, pain, abscesses.	Complete excision	Recovery, 8 mos, unhealed.	1879
14	G.	61	M.	M. G. H.	Caries.	2 mos.	Abscesses.	Complete excision	Recovery, 8 weeks, discharging sinuses.	1879

peared. Could not touch the back of head with the hand. Could not extend the arm completely. Could lift but the lightest weight to shoulder. The great discharge of matter ceased a few weeks after leaving the hospital. The elbow had given no trouble other than the stiffness in extension.

CASE X. Operator, Dr. Samuel Cabot. Caries of the elbow. Excision. Recovery. Vol. CLXXXV, p. 128.

Man, aged fifty-four years, has had a swollen and sinus discharging elbow-joint for fifteen years. Joint excised by the usual method and dressed with a Lister dressing. At the end of twelve weeks discharged, with one open sinus, and having a little motion in elbow and use of hand.

Nine years after discharge. Patient writes as follows: "I can lift and do any heavy work with the arm, mow, dig, and shovel as ever. Perfect use of hand. Sinus at elbow which existed when discharged, closed after a little bone came out, at the end of four weeks."

CASE XI. Operator, Dr. C. B. Porter. Necrosis of ulnar with ankylosis of elbow-joint. Excision. Recovery. Vol. CLXXXVIII, p. 175.

Girl, aged eleven years, for six months previous to operation had a swollen elbow with discharging sinuses. Excision done by the usual method. Lister dressing. Discharged at the end of twenty-five weeks with wounds all healed and some motion of elbow. No abscesses.

Eight years after operation. Patient reports: discharge ceased after she was out of the hospital two weeks. Fingers and elbow are a little stiff yet. Can carry on easily by work in a woolen mill. Cannot make much of a blow from the shoulder.

CASE XII. Operator, Dr. R. M. Hodges. Caries of the elbow joint with ankylosis in an extended position. Excision. Recovery. Vol. CXLIV, p. 170.

Woman, aged twenty-five years, has had for ten months a swollen elbow, discharging pus through one fistula over the outer condyle. Probe enters the joint about half an inch. Elbow excised after the usual method, Lister dressing. Discharged at the end of six weeks, all wounds healed and able to use elbow completely.

Heard from a year and a half later, and the excised elbow-joint is said to be "little inferior to the original."

Seven years after the operation. Elbow in good condition. Does all ordinary work with ease. Touches hand to back of head. Fingers and hand supple and useful. Hand held in position of semi-pronation. Complete rotation of radius impossible. Flexion and extension good, no hyper-extension. Can lift an ordinary chair to waist with excised arm. Puts hand behind back with ease. No discharge from elbow that amounts to anything, occasionally, for a few days, some matter comes out, but at present no evidence of inflammatory disturbance about the joint.

CASE XIII. Operator, Dr. R. M. Hodges. Caries of elbow. Excision. Recovery. Vol. CCXVI, p. 47.

Girl, eighteen years old, has had a stiff elbow for many years. Nine months ago, it was swollen, tender, and sinuses led into the joint. Joint was excised and abscesses curetted. Lister dressing. Discharged in sixteen weeks with a few superficial ulcers, and a considerable range of motion in joint.

Four years after the operation, 1888, the patient writes: "My arm has grown quite strong. I sew on very heavy goods. There is no stiffness of the fingers. I can touch the back of my neck with my hand. My arm is almost as straight as the right one. I can lift a hod of coal as high as my hip. The discharge ceased one year after I left the hospital. The elbow has not given me any trouble."

CASE XIV. Operator, Dr. H. H. A. Beach. Caries of elbow. Excision. Recovery. Vol. CCXVI, p. 1.

Girl, aged fourteen years, for nine months has had some loss of flexion of elbow, and a sinus below internal condyle. Joint was excised after the usual manner. Lister dressing. One month after the operation patient discharged with almost complete extension and good flexion of arm, and by passive motion there is some rotation.

Four years after operation. Can sew, crochet and write. Works at millinery. No sign of stiffness. Can touch the back of neck without difficulty. Cannot completely extend arm. Discharge ceased after a few months.

CASE XV. Operator, Dr. J. C. Warren. Caries

TABLE V.—Cases of Compound Fracture into the Elbow-Joint Excised either partially or completely.

No.	Name.	Age.	Sex.	Where done.	Disease.	Duration.	Condition.	Operation.	Immediate Result.	Year.
1	L.	45	M.	M. G. Hosp.	Compound transverse fracture of humerus above condyles and into joint.	1 hour.	Soft parts badly lacerated.	Complete excision	Recovery, 11 weeks, granulating wound, can bend arm to right angle.	1879
2	G.	32	M.	M. G. H.	Compound crush of lower end of humerus.	1 hour.	Radius and ulnar uninjured.	Complete excision	Recovery, 4 weeks, healed solidly.	1880
3	K.	27	M.	M. G. H.	Compound crush of lower end of humerus.	13 days.	Abscess in forearm.	Removal of lower end of humerus	Recovery, 14 weeks.	1880
4	J.	41	M.	M. G. H.	Compound comminuted fracture of olecranon and external condyle humerus.	2 hours.	Soft parts crushed.	Complete excision	Recovery, 9 weeks, good motion, healed.	1882
5	R.	14	M.	M. G. H.	External condyle crushed, muscular spiral nerve bruised and in wound, joint opened.	3 hours.	Soft parts badly lacerated.	Excision of lower end of humerus, suture of muscles	Recovery, 10 weeks, motions all good.	1884
6	M.	26	M.	M. G. H.	Compound fracture into joint, with pin-hole opening.	4 days.	Joint full of pus.	Complete excision	Recovery, 5 weeks, motions fairly good.	1885
7	D.	22	M.	M. G. H.	Elbow crushed to the bone both behind and in front.	1 hour.	....	Complete excision	Recovery, 9 weeks, small granulating wound.	1886
8	O.	30	M.	M. G. H.	Compound fracture of the olecranon into the joint.	2 days.	....	Complete excision	Recovery, few weeks, Abscess, redness and swelling of the arm. Died 14th day with fever and delirium.	1887
9	M. G.	30	M.	M. G. H.	Compound comminuted fracture of the humerus lower end into the joint.	2 hours.	....	Complete excision	Recovery, few weeks, Abscess, redness and swelling of the arm. Died 14th day with fever and delirium.	1887
10	J. F. C.	26	M.	M. G. H.	Compound comminuted fracture of the head of radius and ulnar-joint opened.	1 hour.	Bones crushed.	Complete excision	Recovery, few weeks, Abscess, redness and swelling of the arm. Died 14th day with fever and delirium.	1887
11	J. F. B.	22	M.	M. G. H.	Compound fracture of right elbow and left wrist.	1 hour.	External epicondyle and head of radius comminuted.	Complete excision of right elbow and amputation of left forearm	Died following day, "cardiac failure."	1876
12	A. J.	62	M.	M. G. H.	Compound dislocation of the ulnar.	2 mos.	Ulnar projected posteriorly 3 ins., covered with granulations.	Partial excision	Recovered.	1870
13	B. S. W.	53	F.	M. G. H.	Compound fracture of olecranon, opening the joint.	1 hour.	....	Complete excision, brachial artery ligated	Died at end of 4 wks., septicæmia.	1870
14	G. S.	35	M.	M. G. H.	Compound comminuted fracture of the elbow-joint.	1 hour.	Shaft of ulnar badly broken.	Complete excision	Recovery, could move arm quite freely at end of 6 weeks.	1873
15	G. J.	39	M.	M. G. H.	Compound fracture of humerus.	1 hour.	....	Partial exc'n 3 ins. from humerus	Recovered.	1873

TABLE VI.—Cases of Ankylosis of the Elbow-Joint Excised.

1	Q.	11	M.	M. G. H.	Ankylosis of elbow.	6 mos.	Elbow-joint stiff, muscles of arm and forearm wasted.	....	Recovery, 5 weeks, could flex and extend arm, and hold 2 lbs. at arm's length.	1879
2	H.	31	M.	M. G. H.	Injury, ankylosis, caries.	6 years.	Ankylosed elbow, dorsal Pott's disease.	....	Recovery, died 1 year later, could use arm for light work.	1879

TABLE VII.—Case of Gunshot Wound of Elbow-Joint Excised.

1	J. T.	23	M.	M. G. H.	Gunshot wound of elbow-joint.	1 week.	Arm swollen, a sinus each side the joint corresponding to entrance and exit wounds.	Complete excision	Death in 6 weeks, septicæmia.	1862
---	-------	----	----	----------	-------------------------------	---------	-------------------------------------------------------------------------------------	-------------------	-------------------------------	------

of elbow. Ankylosis. Excision. Recovery. Vol. CCXXVIII, p. 137.

Boy, aged nineteen years, has had pain for two years in elbow-joint, which became swollen. Abscess opened. Excision of joint after the usual method. Lister dressing. Discharged in five weeks with some motion in joint and wound nearly healed.

One year from operation. Can do very little heavy work. No stiffness of fingers. Can touch the back of neck with hand. Can straighten arm. Can lift a light weight from the side up to shoulder. Can strike a fair blow from shoulder. Discharge ceased from elbow soon after left hospital. Has some pain in elbow yet.

CASE XVI. Operator, Dr. A. T. Cabot. Caries

of elbow-joint. Excision. Recovery. Vol. CCXXXI, p. 160.

Boy, aged twelve years, has had swelling and pain on motion in elbow-joint for one month. Abscess found and was opened. Joint was then excised after the usual method. Discharged in eight weeks, wound healed. Some motion in joint.

At the end of one year. Can do all ordinary work with arm. There is no stiffness of the fingers. Can touch the back of head with hand. Can straighten arm completely, but cannot flex it quite as far as the well arm. Can strike a good blow; power of triceps is good. The discharge of matter ceased before he left the hospital and has not troubled him since. Elbow has never given any trouble.

The group of cases recorded in Table No. III is extremely valuable. I know of no other excisions of the elbow for disease since the antiseptic method of wound treatment has been in common use in which the end results have been studied in such detail excepting those reported from this same hospital in 1877. The propriety of excision of the bones of the elbow in a young adult with caries of that joint, may by some be called in question, but by none if the results shown here are considered.

Each of these eight cases was over eleven years of age. Four were men and four women. The caries had lasted in each case for one or more months. All were treated to a complete excision. The length of time which has elapsed since the operation was one year in two cases, four years in two cases, and in the remaining four cases three, seven, eight and nine years, respectively. In all the cases the details of the present condition are given, and it will be seen that a useful joint with motion in every case exists.

Disease (tubercular caries) of the elbow-joint usually runs a very slow course, lasting for two, three or more years, and the usefulness of the arm at the end of this time is often greatly impaired because of ankylosis of the joint.

These cases speak eloquently for an early and complete excision with removal of all the diseased bone. Contrary to recent advice that "in excision for elbow disease, as a rule, ankylosis is aimed at as the best possible result, so that passive motion is not to be considered,"<sup>2</sup> I believe that these cases demonstrate, as far as it is possible for them to, the possibility and desirability of obtaining a movable joint.

In a previous study of chronic disease in another joint in children<sup>3</sup> it was shown that partial operations upon carious bone at the ankle and tarsus are not attended with as satisfactory results as are thorough removals of all the diseased foci.

The anatomical arrangements in the foot are such that infection is invited from bone to bone and joint to joint, of the tarsus, and complete removal of the disease without the removal of an entire bone, is almost impossible. Whereas at the elbow there is greater certainty of complete removal of the disease because of the ease with which it can be made accessible. In all these cases a complete excision was done with no recurrence of the disease.

The cases tabulated in Tables IV, V, VI and VII, are the remainder of the unpublished cases excised at the hospital. The end results could not be traced. They are published that they may be recorded in all the details accessible, and with the hope that they may be suggestive to any interested in a study of excision of this joint.

These tables, together with the published cases previously mentioned, make a complete report of the excisions of this joint done at the Massachusetts General Hospital from the opening of its records to the year 1888.

**CENSUS OF INDIA.**—The returns of the census in India, which are just completed, show the population of the Indian Empire to be 285,000,000, being an increase of fully 20,000,000 since 1881.

## SOME FORMS OF AMENORRHEA AND THEIR TREATMENT.<sup>1</sup>

BY F. H. DAVENPORT, M.D.,  
Instructor in Gynecology, Harvard Medical School.

AMENORRHEA is like other disorders of menstruation merely a symptom of some pathological condition. Yet more than other abnormalities like dysmenorrhea and menorrhagia, it has a right to be considered a definite disease. In the first place its causes are not so evident nor so easily discovered. Until our knowledge of the relation of menstruation to ovulation is greater than we at present possess, a large proportion of the cases of absence of menstruation which we meet will be inexplicable. If we believe that menstruation presupposes ovulation then our cases will be accounted for in one way: if we accept the theory that the two processes are independent of each other, we shall explain them in another way.

In the second place in very many of the cases of amenorrhea which we are called upon to treat, the absence of this function is the sole symptom. It is not one of a group which taken together in their just proportion enable us to find the determining cause. It is very often entirely unassociated with any local pathological condition which can be appreciated by even the most educated touch.

Therefore, it is worth our study, and we shall make greater progress in our knowledge of it, if we study it as an entity at the same time realizing that it is but a symptom of some pathological conditions which are yet obscure, but which closer observation and more extended research will enable us to solve.

What has just been said is pre-eminently true of so-called "primitive" amenorrhea, by which is meant a condition where the function has never been established, in contradistinction to "acquired" amenorrhea where after the establishment of the function and its continuance for a longer or shorter time, it ceases. These latter cases are more apt to be associated with other definite symptoms which afford a clue to their true cause.

A girl may be said to have amenorrhea when she has reached the age of sixteen or seventeen without the establishment of the function. The average age of the appearance of menstruation in this climate and among the population of our cities and large towns being at about thirteen and a half or fourteen years, a margin of two to three years should be allowed for individual variation. Beyond that age, especially if the girl be otherwise fully developed, the absence of the catamenia should be regarded as abnormal. That does not, as will later on appear, imply that the patient needs treatment.

The non-appearance of menstruation is, especially among the lower classes, looked upon with alarm. The popular idea is that it will lead to consumption. With this idea many such cases will be brought to the notice of the physician. There is some excuse for this opinion on the part of the unscientific laity, inasmuch as the majority of girls who reach the age of seventeen without menstruation are then anemic, and apt to show functional disorders of heart or stomach. An additional reason is found in the fact that in the late stages of phthisis menstruation does cease, and the illogical inference is drawn that amenorrhea stands in some causative relation to consumption.

<sup>1</sup>Read before the Boston Society for Medical Observation, January, 1891.

<sup>2</sup>Reverford and Lavery: *Orthopedic Surgery*, New York, 1890, p. 140.

<sup>3</sup>A report of eighteen cases of chronic disease of the ankle and tarsus. *Boston Medical and Surgical Journal*, January 30, and February 6, 1890.

When such a case presents itself, there are a few leading questions which will determine our course of conduct in regard to it. First, does the patient complain of symptoms directly referable to absence of menstruation? Are such general symptoms present, as rush of blood to the head, persistent headache, palpitation of the heart, dizziness, frequent nose bleed, etc? or local symptoms of periodical attacks of pain in the lower abdomen, leucorrhœa, painful swelling of the breasts, and disturbances of micturition? If not, and the patient is robust, has a good color, and is well-developed, no treatment need be instituted, the assurance being given that in time the function will become established.

If, however, the patient is evidently suffering in consequence of its non-appearance, treatment is indicated. In the majority of such cases general measures are sufficient, and any local interference, even an examination should be avoided. If there have been for some months distinctly marked molimina, the question of a possible atresia should be settled, but the examination to determine this point need be very slight. It is sufficient to slightly separate the labia until the hymen becomes visible. Usually any abnormality can readily be seen, but if any doubt exists, the handle of a cotton stick, which is a little smaller than a lead pencil, can be passed into the vagina without pain or the slightest violence to the hymenal ring.

As regards general treatment, the main reliance is in my opinion, to be placed on iron. Easy assimilation and absence of constipating effects should govern us in the choice of the form of iron to be used. Except for these subordinate advantages no one preparation of iron has, as far as my experience goes, any special advantage over another in stimulating the function of menstruation.

Other drugs have acquired a reputation as emmenagogues, such as permanganate of potash and binoxide of manganese, but they have probably no direct effect on the uterus or ovaries, and their value as a tonic is less than that of iron.

It is unnecessary to more than allude to the importance of observing the laws of hygiene, moderate exercise, good food, avoidance of excitement, and regulation of digestion.

Where such general measures as the above fail, some local treatment may be advisable, and on the border line between them lies electricity. This agent has been used for a long time, and as a means of stimulating the activity of the pelvic organs where more direct treatment is inadvisable, has no equal. Of the two principal kinds of electricity galvanism or faradization, the latter has, in my experience, proved the most efficacious. It may be applied from the abdomen through to the back, placing the abdominal pole, which may be indifferently either positive or negative, alternately over each ovary, or over the uterus itself. Where there is no objection to treatment per vaginam, a much more direct and efficacious application may be made by placing one pole on the cervix and the other on the abdomen over the uterus.

The causes of acquired amenorrhœa are often obscure, and even where the cause is known the explanation of its mode of action is still more difficult.

The most common cause of amenorrhœa is pregnancy, yet in the present state of our knowledge of the physiology of ovulation and menstruation, who will attempt to explain the cessation of the catamenia

during that process? Does ovulation cease, or does it persist, while the ova, unable to reach the uterine cavity, perish in the tube? Does menstruation cease because no ova are ripened, or because the ova not gaining an entrance to the uterus, there is no exfoliation of the outer layers of the mucous membrane, accompanying death and expulsion of the blighted ova?

The same problems, only without the mechanical explanation which exists in the case of pregnancy present themselves for solution in amenorrhœa from other causes.

A few cases of amenorrhœa present themselves where a mental shock seems to be the determining cause.

A writer in a late number of the *British Medical Journal* calls attention to this subject, and cites a number of cases bearing on this point. While in a certain proportion of his cases some other explanation might be given, yet in all of them the shock seems to have had some influence. I have seen two or three examples of this. In one there was amenorrhœa for a number of months following the loss of the patient's two only children of diphtheria. In another, some family disgrace, the nature of which I did not learn, was followed by complete cessation of the catamenia for over two years. In the latter case there was atrophy of the uterus, it measuring only two inches in depth, and although after two months of treatment by electricity, the menstruation has not appeared, the uterine cavity has increased half an inch in depth, and there have been very decided menstrual molimina.

Persistent amenorrhœa sometimes follows confinement even though the woman does not nurse her child. Here the pathological condition seems to be superinvolution, as in the cases that I have seen, there has invariably been found a small thin uterus.

I have lately had under treatment a patient who has not menstruated for fifteen months following her last confinement, though she did not nurse, and no new pregnancy had supervened.

We are all familiar with that form of amenorrhœa which occurs, especially in our emigrant population, from the change of climate. That the sea voyage is not the prime factor is shown by the fact that a similar cessation not infrequently occurs in young women from Canada and the Provinces who come to the States by land. I am inclined to think to some extent the changed mode of life, better food, less outdoor exercise and our better heated houses may account for it.

There is at times a direct connection between amenorrhœa and obesity. Analogous facts are the tendency of women to put on flesh after the menopause, and after the artificial menopause following the removal of the ovaries by laparotomy, observations which hold true of the lower animals as well. It is not easy in all cases to trace the exact sequence of events, but it seems probable that more often the amenorrhœa is the cause of the obesity, than the reverse. Measures directed to reducing the fat have usually proved futile, and have not resulted in a re-establishment of the function. (This being the fact, we must look for some underlying cause for the scanty or suspended menstruation, and I must confess to complete failures in the cases which I have observed. The usual history in such cases is a gradual diminution in the amount of the flow, after a time ceasing altogether, and a progressive increase in weight.)

An interesting fact in the symptomatology of many cases of amenorrhœa from whatever cause, is the apparently vicarious character of leucorrhœa. I have several times been told that at regular intervals of time corresponding to what would be normal menstrual periods, there was an abundant leucorrhœal discharge lasting several days. I remember one case where this discharge was accompanied by pains which were perfectly characteristic of those usually accompanying the menstrual period. The usual symptoms are those we observe in connection with the menopause, disturbances of the circulation, being the most prominent. Headache, flushing of the face, palpitation of the heart, weight and pressure in the pelvic region, and a tendency to grow stout are the most common.

The treatment of acquired amenorrhœa does not differ essentially from that of the primitive form. The same rules hold for treatment by general measures alone, or by a combination of general and local. In the cases of amenorrhœa accompanied by atrophy, electricity would be the sheet anchor, and the faradic current which directly stimulates the muscular fibres of the uterus has been the most efficacious in my hands.

I have a very few times used a galvanic intra-uterine stem, but I never should resort to its use where it is possible to use the direct application of a strong current three or four times a week. The former is too mild and uncertain.

In the cases accompanied by obesity I should of course direct my efforts to reducing the fat as far as possible. I have never been able to carry out any elaborate course of treatment directed to this end, such as have been advocated in Germany by Oertel and Ebstein. These might prove more efficacious than my trials have been.

For the other varieties spoken of, general tonic treatment combined with local in suitable cases, will usually result in cure.

The cessation of menstruation is not in all cases an evil. On the contrary there are cases where its absence must be looked upon as a conservative provision of nature to prevent unnecessary waste. In anæmic subjects, and in persons recovering from long and debilitating sickness, it would be unwise to institute active treatment for bringing this function into activity, unless the direct results of its cessation in the form of pain or disturbances of the circulation outweigh in importance the bad effects of the loss of blood.

Just how far this principle may be carried is a little doubtful. Gehring, of St. Louis, has at two recent meetings of the American Gynecological Society advocated stopping menstruation by therapeutical measures, first in cases of menorrhagia and metrorrhagia, then in cases of scanty menstruation, and paradoxical as it may seem in cases of amenorrhœa, that is, in such cases he does "his best to remove the disease or diseases upon which the amenorrhœa depends whether local or general, and as soon as the power to menstruate has returned, he uses the tampon to lessen or prevent the flow." His explanation is, that as temporary amenorrhœa occurs generally in anæmic or chlorotic individuals, it will easily be understood that the first step is to remove the cause, and the second to promote or render possible the convalescence.

The view of Dr. Gehring are extreme, but their explanation is found in the fact that he considers bloody menstruation a pathological process. Those

of us who do not agree with this view, and I imagine that is the attitude of most of us, would hardly go so far as Dr. Gehring, yet that the flow may be safely and wisely repressed or prevented in not a few cases, will, I think, be conceded by all. I have tried this method in some instances, using the tampon, and rest in bed if necessary, and have become satisfied that it may be of great value. While I have not had the brilliant results claimed for the method by Dr. Gehring, yet I have, except in one case, had no unpleasant results, and have seen marked improvement follow it. In the case I speak of, the presence of the tampon at the time the catamenia were expected brought on such intense pelvic pain and headache that the tampon had to be removed, and menstruation allowed to begin, though after continuing for a day or two it was checked by a reapplication of the tampon with the happiest results.

The treatment of this subject in this brief paper has of necessity been such that its true character as a mere symptom of pathological conditions often obscure, has been thrown into the background. Progress in the true understanding of its real significance will alone enable us to be more successful in our therapeutical measures.

#### AMENORRHEA: CLINICAL REPORT OF FOUR CASES SUCCESSFULLY TREATED BY GALVANISM.<sup>1</sup>

BY C. P. STRONG, M.D.

*Physician to Out-patients, Massachusetts General Hospital; Assistant Surgeon, Free Hospital for Women; Assistant in Gynecology, Harvard Medical School.*

PRELIMINARY to the report of the cases presented this evening and to confine the discussion, I wish to state that the single subjective symptom of absence of menstrual flow, unaccompanied by physical change, has never seemed to me an indication for treatment. There is, however, one type of patients where various subjective symptoms, especially disturbances of the vasomotor system and other reflex phenomena are presented. Physical explanation, as by mal-development, displacement or recognizable abnormality in the uterus itself or its adnexa is lacking. The patients are strong, healthy-looking women, not the victims of anæmia or organic disease. When married they are sterile. The reflex nervous symptoms presented are akin to those accompanying the menopause. Cephalic pains, inaptitude for the usual employments, depression, perhaps, even tinged with melancholy, sleeplessness, and kindred disorders.

As regards the medical treatment of these cases, it may, regarding my own experience, be dismissed with a word—useless.

As regards the local treatment, whatever the means adopted, certain cases will be found entirely obstinate, others amenable at one time may fail at another, while a not inconsiderable number will always be affected by the method suggested in this paper, a method devoid of danger even should its good results not be manifested. Until I employed the galvanic current I had met with no success in the treatment of these cases by any local measure. Since adopting this, I feel a reasonable degree of confidence in assuring patients of relief to their subjective symptoms, although I cannot always promise the certain induction of the catamenial flow.

<sup>1</sup> Read before the Boston Society for Medical Observation, January, 1891.

**CASE I.** Mrs. X., twenty-nine, consulted me in the spring of 1887. She was in all ways a perfect type of womanly development. There was nothing in her history pointing to uterine disturbance until complete cessation of menstruation three months before her visit. Coincident with this she began to grow stout. The amenorrhœa did not disturb her, but distressing occipital and vertical headaches, sleeplessness and general nervousness ensued. General hygienic and therapeutic measures, for one month, gave no relief. Selecting the day when the catamenia would naturally appear, I applied galvanism. Following the immediate brownish discharge there was a scanty menstrual flow. Bi-weekly sittings were continued through the month, and the subsequent periods were normal in all respects, and continued so until October, 1890 (three and a half years). The headaches and nervous symptoms and the extra flesh all disappeared, not returning during this interval. When I saw her in October she was confined to her bed, suffering as before from reflex symptoms. Circumstances made it necessary that she should be attended for some time before it was possible to employ the former treatment. She improved but very little. Menstruation had been absent two months, but the exact date for its reappearance not being known, bi-weekly applications were made. Menstruation followed the third treatment, and has since continued, a single application being made on the date at which the flow could be expected. The other symptoms are also cured.<sup>2</sup>

**CASE II.** Mrs. T., twenty-six years of age, sterile, married five years. Large, finely formed woman, accustomed to out-door life and much exercise. Consulted me July 23, 1890. Last menstruation, March 15th. Never irregular before. Suspected pregnancy, and came to me for confirmation, although presenting none of the subjective symptoms of the condition. Nothing in any way abnormal about the pelvic organs could be detected. There were many reflex nervous symptoms, and the patient said she was growing stout rapidly. A single application was followed by menstruation, which continued regularly until November. Then there were two applications more required, and the flow has normally appeared twice since.

**CASE III.** Mrs. J., twenty-eight years of age, married seven years. One child six years ago. Had always been irregular, the inter-menstrual period being five to seven weeks. This patient had very marked neurotic manifestations, almost "fixed ideas," a direct inheritance, and the period of delay beyond the regular time was one of distressing exaggeration of these symptoms, accompanied by great irritability.

March 20, 1890, the date of the first visit, galvanism was applied. The flow, then three weeks overdue, appeared within twenty-four hours.

In April, following bi-weekly applications, menstruation was six days late.

May. Exactly twenty-eight days.

June. Applied once each week during the month; one week overdue.

July. Applied twice at the expected date; appeared in twenty-eight days.

August. Applied only once; two weeks overdue.

September. No galvanism, but plastic operation performed; menstruation not recorded.

November. Applied once, just at the expected date; immediately appeared.

<sup>2</sup> April 10, 1891. Menstruation still regular.

December. Applied twice, just at the expected date; menstruation three days late.

The full record of this case demonstrates certainly the action of the galvanic current in abridging by a considerable interval the usual delay in the appearance of the flow, and also it relieved to a very considerable degree (according to the patient's statement) the nervous symptoms attendant on this delay.

**CASE IV.** Miss D., twenty years old. Menstrual history one of great irregularity. The usual history was appearance of the flow twice in three months and then no more for four, six or even ten months.

March 14, 1889, date of first visit. Had not menstruated since July, 1888, eight months. The flow appeared at once, normal in amount; reappeared again the next month; then was absent three months.

October 20, 1890. Has had no flow since July. Single application followed by scanty menstrual discharge, October 22d.

November 24th. Bi-weekly application; normal.

December 25th. Bi-weekly application; normal.

These cases represent a selected type of patients as described previously; and are not intended to include any and all cases of amenorrhœa to which I have applied galvanism with, as a rule, no immediately successful results.

The method of application has been the introduction of an intra-uterine electrode insulated to within an inch of its point which is made of platinum, a broad abdominal electrode of zinc covered with cotton. The current in my first case was not measured, but in all the later cases varied from fifteen to forty milliamperes, being carefully measured. The positive pole was abdominal and applied alternately over either ovarian region for fifteen minutes. Immediately, and for about twenty-four hours after the application, there was a brown discharge from the uterus. There was a marked difference in the patients with regard to the tolerance of the current. Occasionally very disagreeable crampy pains were produced, but I have seen no other ill effect.

## RECENT PROGRESS IN SURGERY.<sup>1</sup>

BY H. L. BURRELL, M.D. AND H. W. CUSHING, M.D.

### CANCER OF THE BREAST.

THE results of a radical operation (amputation of breast, dissection of the axilla, removal of the pectoral fascia) in thirty-nine cases, are reported by Bihler.<sup>10</sup> The final results are interesting. Sixty-five per cent. were found to have died. In 12.5 per cent. the disease has recurred, but the patients still live. Twenty per cent. are cured, among whom three have lived more than three years since the operation, and two have lived more than two years. The interval during which these operations were performed is from 1886 to 1888 inclusive.

### THE ETIOLOGY AND SURGICAL TREATMENT OF SEPTIC PERITONITIS.

Reichel<sup>14</sup> has contributed an interesting article on this subject. He thinks the absence of evidences of peritoneal inflammation at autopsies after laparotomies is not to be considered proof that death was not due

<sup>1</sup> Continued from page 360.

<sup>10</sup> München, Dissertation, 1890: Schmidt Jahrb., 1890, vol. 227, p. 261.

<sup>14</sup> Deutsche Zeitschr. f. Chir., Bd. xxx, p. 1-81.

## RESECTION OF THE CÆCUM FOR CARCINOMA.

Dr. Senn<sup>18</sup> has contributed a report of two cases in which this operation was performed, and comes to the following conclusions:

(1) Resection of the cæcum for carcinoma can be done with a fair prospect of a permanent cure if the operation is performed before the infiltration of the retro-peritoneal and mesenteric glands has occurred.

(2) Ileo-colostomy with absorbable perforated approximation-plates is the best method of restoring the continuity of the intestinal canal after excision of the cæcum.

(3) The best material for approximation-plates is decalcified bone preserved in an antiseptic solution.

(4) Hygroscopic and indestructible or inabsorbable material should not be used in the preparation of approximation-plates or rings, as the former may cause pressure-gangrene, and the latter may prove a source of danger by remaining permanently as a foreign body in the organ in which it has been introduced.

(5) Ileo-colostomy without resection of the cæcum is indicated in cases of intestinal obstruction from inoperable carcinoma of the cæcum, irreducible invagination without perforation or evidences of gangrene, and in cicatricial stenosis in the ileo-cæcal region not amenable to a plastic operation.

(6) Scarification of the serous surfaces interposed between the bone-plates, is the most reliable means of hastening the formation of adhesions and of shortening the process of definite healing.

(7) Resection of the cæcum and ileo-colostomy with or without enterectomy, should be done through a lateral incision, extending from near the middle of Poupart's ligament to a point half-way between the anterior superior spinous process of the ilium and the umbilicus.

(8) Suturing of the serous surfaces just beyond the margins of the bone-plates renders material aid in maintaining apposition between the serous surfaces which it is intended to unite, and furnishes an additional safeguard against fecal extravasation.

(9) Anchoring of the approximated parts in the ileo-cæcal region with a mesenteric-peritoneal suture, should be done in ileo-colostomy after resection of the cæcum.

## HIGH EXTIRPATION OF THE RECTUM.

C. Lauerstein,<sup>19</sup> Hamburg, reports a successful case in which a carcinomatous rectum was resected according to the Kraske-Schede method. The left lateral portion of the sacrum was removed as high as the fourth sacral foramen. He claims that a higher resection of the sacrum affects a motor branch of the fourth sacral nerve supplying the fundus of the bladder and the prostate. This differs from other operators who claim that the sacrum can be resected as high as the third foramen without injury to important nerves.

## ON THE SYMPTOMS OF CHRONIC OBSTRUCTIONS OF THE COMMON BILE DUCT BY GALL-STONES IN REFERENCE TO SURGICAL INTERFERENCE.

In a paper which considers the prominent group of symptoms associated with gall-stones, Osler<sup>20</sup> has brought forward what he terms a "symptom-group," which he considers characteristic of the existence of

gall-stones in the common duct. The group of symptoms is as follows:

(1) Jaundice of varying intensity, deepening after each paroxysm, and which may persist for months or even years.

(2) Ague-like paroxysms characterized by chill, fever and sweating, after which the jaundice usually becomes more intense.

(3) At the same time of the paroxysms, pains in the region of the liver, with gastric disturbance.

He records eight cases of chronic obstruction of the bile duct, and draws the following conclusions:

(1) Chronic obstruction of the common bile duct is often accompanied by an intermittent pyrexia, associated with a symptom-group of the greatest diagnostic importance.

(2) This pyrexia is not usually the result of suppuration, as has been supposed, but occurs with a catarrhal cholangitis.

(3) That it arises from the absorption of a ferment, produced in the ducts, is rendered highly probable by the discovery of micro-organisms, both in the catarrhal and in the suppurative cholangitis.

(4) While recovery may follow, even after months or even years, a fatal event is only too common.

(5) A recognition of the importance of this intermittent pyrexia and its associated symptom-group, as diagnostic of obstruction of the common duct by gall-stones, should, in the present condition of hepatic surgery, lead to more frequent operative interference in these cases.

## PROSTATECTOMY LATERALIS.

V. Dittel,<sup>21</sup> Vienna, proposes to relieve a prostatic obstruction due to unilateral or bilateral hypertrophy by resecting the hypertrophied area through the perineal and ischio-rectal fossa, the incision for which he describes as starting from the coccyx, curving around the anus and terminating at the perineal centre. Through this the prostate is dissected from the rectum and the obstruction removed. He reports no case of this having been done on the living subject, and his description does not impress one that this method has any especial advantages or even equals the supra-pubic method.

## CASTRATION OR RESECTION OF THE EPIDIDYMIS FOR TUBERCULOSIS.

A careful investigation of fifty-three cases by Dr. E. Dürr at Brun's Klinik, with reference to Bardenhauer's statement (some years ago) that resection of the affected epididymis was a preferable procedure to castration, has caused him to form the following conclusions:<sup>22</sup> That the subsequent affection of the remaining testis necessitating double castration is by no means so frequent as reported by Bardenhauer. That the partial operation, namely, the resection of the epididymis as already stated by Kocher, is not a desirable operation, for it by no means gives such protection from recurrence as the complete castration.

## EXTIRPATION OF TUBERCULAR VESICULAR SEMINALES.

Ulmann<sup>23</sup> believes that this operation is indicated in cases of primary tuberculosis of the testes or epididymis when the vesicular seminales is invaded or when

<sup>18</sup> Journal of the American Medical Association, June 11, 1890.

<sup>19</sup> Deutsche Med. Wochenschrift, 1890, xvi, 2.

<sup>20</sup> Annals of Surgery, March, 1890.

<sup>21</sup> Wien. klin. Wochenschrift, 1890, lli, 18, 19.

<sup>22</sup> Beitr. zur klin. Chir., 1890, vi, 2, p. 451.

<sup>23</sup> Central. f. Chir., 1890, xvii, 8.

the vesicular seminales are primarily involved; a rare occurrence, and recommends the removal of the diseased tissue. Resulting sterility, the objection to such procedures, is considered as having no influence as contraindicating this method, since this condition is usually already produced by the disease. He employs the Zuckerkandl operation, that is, a curved incision between the scrotum and anus, the concavity towards the sacrum.

#### THE AFTER-TREATMENT OF SKIN-GRAFTING BY THE THIERSCH METHOD.

In an interesting article<sup>24</sup> V. v. Hacker calls attention to the extreme readiness with which recently grafted healed surfaces yield to external irritation, blows, etc., and ulceration recurs. Hence he claims that it is of considerable importance that such freshly healed surfaces should be carefully protected for a considerable time subsequent to the healing of the ulcerated surface, especially where the skin or cicatrix is immovable. He recommends a carefully applied flannel bandage, and later, massage. Commencing ulceration should be at once re-grafted.

#### THIERSCH SKIN-GRAFTING IN CARCINOMATOUS<sup>25</sup> ULCERATED SURFACES.

E. Goldmann's<sup>25</sup> investigations confirm Kraske's report, and he concludes that the method is practical and of value. He has found it most successful in tumors rich in vessels and poor in cells. The strips of skin to be grafted should be as thin as possible. The influence of such grafts on the growth of the tumor is as yet undetermined.

#### LIGATION OF THE FEMORAL ARTERY AND VEIN.

Zeidler<sup>26</sup> has found that in twenty-five cases of ligation of the common femoral vein, one case of gangrene occurred. Of fifty cases of simultaneous ligation of both artery and vein, gangrene followed in twenty-four. Five cases where the artery alone was ligated two terminated in gangrene. Therefore it is not allowable to ligate the artery in case of injury to the vein as has been proposed. When both are injured of course this is unavoidable, and gangrene, although to be feared, is not inevitable. He reports two cases where recovery followed the ligation of both vessels.

#### THE CURE OF ANEURISMS BY INDUCING THE FORMATION OF WHITE THROMBI WITHIN THE SAC.

In an address to the Midland Medical Society,<sup>27</sup> William Macewen has presented an extremely interesting series of observations and cures of cases. He brings about a deposition of white thrombi within the wall of an aneurismal sac by the introduction of a pin, which scratches the intima of the sac. The instrument employed is a pin of sufficient length to completely transfix the aneurism, and to permit of manipulation within it. This calibre ought to be as fine as possible, the strength being only sufficient to penetrate the coat of the aneurism and the intervening tissues. This cylindrical pin tapers to a point like an ordinary sewing needle, and has, on its opposite extremity, a somewhat rounded head. As the coats of the aneurismal sacs vary in thickness, these pins must be made of various calibres, as those which may pass readily

through one aneurismal sac may not pass through others with thicker walls. They ought also to be finely polished, not only to facilitate their introduction, but to help to render them aseptic.

Before performing the operation, the skin over the aneurism ought to be carefully cleansed and rendered aseptic. The aseptic pin ought then to penetrate the sac and pass through the cavity until it comes in contact with the opposite side. It ought to touch the opposite side, and no more. Then one of two methods may be employed: either to move the pin over the surface of the inner wall so as to irritate its surface, or to allow the impulse of the blood-current playing on the very thin pin to effect the same object. If the wall penetrated by the pin on introduction be dense, the former method will be preferable, as the force of the blood-current produces such a feeble action on the thin pin as to be insufficient to move it to and fro while it is firmly grasped by a dense wall. After acting thus for ten minutes at one part, the point of the pin, without being removed from the sac, ought to be shifted to another spot, and so on until the greater portion of the internal surface opposite to the point of entrance has been acted upon. This ought to be done in a methodical manner. A single insertion of the pin through the aneurismal sac into its anterior may be sufficient to enable the point of the instrument to come into contact with the greater part of its internal surface, but in some cases punctures from various sides of the external wall may be necessary so as to reach portions of the tumor which cannot be attacked from the first puncture. While the pin is in the aneurism, it is surrounded by a portion of aseptic gauze, dry or moistened with an antiseptic solution. When it is withdrawn from the aneurism, the part ought to be covered with moist antiseptic dressing, preferably a watery solution of carbolic acid, which ought to be maintained for several days.

The period a pin may remain in an aneurismal sac without doing damage is, perhaps, dependent on the individual and the state of the aneurism, but it ought never to exceed forty-eight hours. It is questionable whether all the necessary advantages derivable from the irritation of the wall of the aneurism could not be produced within a few hours. No doubt its retention for twenty-four or thirty-six hours seems to produce a greater immediate effect.

If the aneurism be very large, several pins may be introduced from various points, always allowing a considerable interval to exist between each, otherwise, there might be too much damage to the vessel wall at one spot. In some instances the point of the pin has been engaged in the opposite wall of the aneurism, and has thus produced sufficient irritation. It need scarcely be said that the general health of the individual, the condition of the aneurism, and the surrounding tissues, ought to be carefully examined before commencing the treatment. If there be anything wrong with the health which could be put right before operating, that ought to be done. No one would think, for instance, of introducing pins into an aneurism which was inflamed, or where the tissues in the vicinity of the aneurism were in a state of erysipelas. It would also be necessary to render aseptic any sore which the patient had in other parts of the body.

Dr. Macewen has carefully recorded the cases which he has treated in this manner, and summarizes the results as follows:

<sup>24</sup> Ein Beitrag zum Verständniss der Thierschen Hautverpflanzung und der Heilung, Wien Klin. Wochenschrift, 1890, III, 19, 20.

<sup>25</sup> Schmidt's Jahrb. f. ges. Med., 1890, Bd. 278, p. 69.

<sup>26</sup> Wien Klin. Wochenschrift, 1890, XXVII, 29.

<sup>27</sup> Brit. Med. Journal, November 15, 1890.

"There are here four cases of aneurism, one involving the innominate, one the left subclavian, one the abdominal aorta, and one of the upper part of the femoral, implicating the external iliac. Two of these have been absolutely cured by the induction of white thrombi within the sac. One was so greatly relieved that he was able to resume his work as a locomotive engine driver, and to continue for at least two and a half years thereafter. One died after a month's treatment from asphyxia, when the aneurism was two-thirds healed, and when complete consolidation was within a few weeks of consummation. In the large aneurism of the femoral and iliac the circulation within the vessel was arrested for two hours, during which, treatment was performed on the sac wall. Consolidation resulted in five days, and he was cured in a month. The aortic and innominate aneurism was a month under treatment and had pins inserted on seven occasions. The formation of thrombi occurred rapidly and had formed to a greater extent than was known during the patient's life. The aneurism of the abdominal aorta was a month under treatment, but the aneurism was not cured, the consolidation being incomplete. The aneurism of the left subclavian had pins introduced on nine occasions — it is questionable whether the last five produced any effect or whether they were needed. Consolidation occurred within nine months, and the cure was completed within a year.

"None of these patients had anesthetics administered and they suffered comparatively little pain during the operation. The slowness of the occlusion in the last case, though disadvantageous in some respects, had certain advantages valuable in the presence of advanced arterial disease. It enabled the collateral circulation to become fully established in a very gradual manner before complete occlusion of the sac had occurred, and thus saved the collateral vessels from sudden dilatation by increased blood-pressure. It protected the heart and blood-vessels on the proximal side of the aneurism from the sudden strain which would otherwise have been thrown on them by ligation of the vessels or by sudden occlusion of the aneurism. Though the completion of the cure takes long in certain instances, the aneurism is not left unprotected during that period, as its coats have been lined by white thrombi, forming a firm barrier against further aneurismal extension.

"It is probable that, besides acting locally on the aneurism, in addition, attention to the general state of the individual may facilitate the formation of white thrombi. By placing him in good hygienic surroundings, by limiting or so regulating his diet as to produce an effect upon the leucocytes of the blood, by the administration of drugs, and by keeping the patient in a state of rest — any, or all of these, may have an effect of hastening the desired end. These are some points to be wrought out in the future. It is well, however, that the fact should be established that white thrombi may be induced simply by direct local action without any aid from other directions. No doubt some cases will be found more suitable for this form of treatment than others; in some the white thrombi will form more readily, in some more slowly. Future experience will decide. I trust that this form of treatment will not be indiscriminately employed upon every case of large aneurism, especially upon those which are beyond hope, otherwise the method will become discredited. The very simplicity of the treatment, the facility with which it may be carried out, without even the use of an

anæsthetic, and with a comparatively limited anatomical knowledge, makes this word of caution necessary. The cases of uncomplicated aneurism must be few in which the introduction of an aseptic steel pin into the sac would be productive of harm. Disastrous results would easily follow the introduction of a pin carrying septic matter with it.

"In conclusion, whether this precise method of inducing white thrombi within the sac be received, matters little if we accept the fact that every aneurism contains within itself a potential cure. We have only to devise methods of calling it forth."

(To be continued.)

## Clinical Department.

### A CASE OF CARDIAC DROPSY.

BY F. GORDON MORRILL, M.D.

BRIEF notes of the following case are written, as affording an example of the efficacy of calomel in conjunction with digitalis as a diuretic, and of the good results sometimes obtained by energetic treatment in cardiac dropsy.

W. M., aged twelve, was admitted to the Children's Hospital October 22, 1890, with a history of pulmonary hæmorrhage during the course of a severe and prolonged illness two years previous to the time of entering the house. Since then the boy had attended school regularly and enjoyed fair health until the latter part of August last, when his present attack commenced with dyspnoea on exertion and slight oedema of the feet and ankles.

Present condition: Lips and face a dusky blue; superficial veins of thorax and abdomen much dilated; great oedema of feet, legs and face; ascites; lower halves of both sides of chest flat upon percussion, back and front; respiratory murmur absent over corresponding areas. The apex beat was found to be three-quarters of an inch outside the nipple in the fifth intercostal space. A soft systolic murmur (transmitted to the axilla) was present, and the pulmonic second sound was much accented. In short, a marked example of cardiac dropsy and dyspnoea. Bowels constipated. Urine scanty.

Ten grains of calomel and five of jalap produced two watery evacuations and slight relief of the dyspnoea. Half a grain of calomel and four drops of tincture of digitalis were ordered to be given every third hour throughout the day and night; brandy and milk in small quantities at short intervals.

October 24th. Has passed one hundred and twelve ounces of urine during the past twenty-four hours. Marked relief of dyspnoea. Respiratory murmur faintly audible over lower portions of both lungs. Oedema beginning to disappear. To continue same treatment.

October 28th. The urine has averaged one hundred ounces in quantity during the past four days. No purging or unpleasant symptoms of any kind have attended the treatment, which has been continued without interruption since the date of last entry, and is now omitted as all signs of dropsy and distress have disappeared.

The subsequent history is one of rapid convalescence. The amount of urine voided is so great for a child of twelve, and the relief so speedy, that the case seems worth recording.

## Reports of Societies.

### BOSTON SOCIETY FOR MEDICAL OBSERVATION.

T. F. SHERMAN, M.D., SECRETARY.

REGULAR Meeting Monday, January 5, 1891, DR. J. S. GREENE in the Chair.

DR. C. P. STRONG read a paper on

#### AMENORRHEA CONSIDERED AS A FUNCTIONAL DISORDER.<sup>1</sup>

DR. F. H. DAVENPORT: Before reading my own paper I would like to mention one fact with reference to the use of electricity in these cases. My experience has not been exactly the same as Dr. Strong's in regard to the form of electricity to use. I have used faradization in a certain number of cases, and galvanism also; but the results of faradization in my earlier cases were so good that I have been inclined to use that rather than galvanism. I do not know whether the difference in our results is due to a difference in the class of patients for which it has been used. Dr. Strong mentioned that the class of patients in which he found galvanism of the greatest benefit was in robust and healthy women. My experience has been that faradization has been of the most use in weak, anæmic women, and this may account for the different results in the administration of this agent.

DR. H. F. VICKERY: I would like to ask Dr. Strong if the electricity is applied at the patient's house.

DR. STRONG: I have them come to my office usually. If, however, the patient is very nervous, or if the uterus is intolerant of any treatment, I should prefer to apply it at the patient's house first. Now and then a person is a little faint, but I have never seen the slightest bad effect from the treatment.

DR. A. H. NICHOLS: Although my experience in this class of disorders is extremely limited, I have been none the less interested in Dr. Strong's paper, and chiefly for this reason: he appears to have found a satisfactory mode of dealing with a trouble which, so far as my own observation goes, is always very intractable. In looking back over a period of years I find that immigrants, and particularly healthy Irish girls, form a very large proportion of these cases of amenorrhea unattended by stenosis, displacement or other organic trouble, and where it is therefore quite difficult to explain or account for the disorder. It has sometimes seemed to me that possibly a rough sea voyage might have produced some physical shock or functional derangement; but at other times the report was, that there was no great inconvenience experienced on the ocean trip. In such cases I was led to fall back in a general way on the effects of climatic change, an unscientific and unsatisfactory explanation of the difficulty. To a less extent German immigrants manifest this same functional inactivity, which does not necessarily give rise to any other symptom such as anæmia, headache, nausea, increase of weight, or nervousness, and such cases may harmlessly persist for years. I have observed that where it was possible to send such girls for the summer to the mountains, or more especially to the seashore where they could have sea bathing, in many instances the function was permanently restored; but as a general rule therapeutic treatment has failed. I remember to have tried the permanganate

of potash about the time Dr. Strong read his paper on the use of this agent before the Society, and I was led to conclude that the drug is absolutely ineffective in relieving the condition, if not altogether inert; and the same would apply to almost every other drug. Inasmuch as Dr. Strong's experience has been so different from my own, I shall be glad when additional cases present themselves to give the galvanic current a trial.

DR. AYER: I should like to ask Dr. Strong how far he inserts the electrode into the uterus.

DR. STRONG: To the fundus. The probe I use is one insulated, except the point of platinum, so as not to get any cankerizing action in or about the inner os or the cervical canal. The probe is very similar to the urethral electrode, which would answer perfectly well. I use a broad zinc plate covered with cotton for the abdominal electrode. This has been in a measure a matter of experiment, and I have not quite decided what would be the best. The results obtained being very good, I have continued with those I first used.

I would like to say a good word for the biniodide of manganese in cases of amenorrhea which are dependent on a moderate degree of anæmia, that is, not such as to require iron, but where perhaps menstruation has been delayed because the patient is just a little bit run down. In such cases I think it oftentimes acts better than any other form of tonic. I use it in two-grain doses every four hours. The patient is directed to begin the use of it in the doses mentioned a week before the expected period, continuing it up to the time the period is due. If the period appears, it is discontinued. If it does not appear, the drug is continued until I feel sure it will be practically inert.

I should like to say a word about the cases to which Dr. Nichols alludes. In my service at the Massachusetts Hospital there are a number of these cases of amenorrhea following immigration. Unless I find that they are suffering in some other way, I do not attempt to do any thing for this symptom. I think they will come round all right, and they do not suffer. Now and then there is a simple form of anæmia, of which amenorrhea perhaps is one of the symptoms, and following up those cases I have found that in a certain number of them, after two or three months have gone by, there seems to be a very decided anæmia ensue. Then tonics often help, but the majority of cases do perfectly well without treatment, and the reason they come in is simply because they are frightened on account of their menstruation not appearing, and fear that they will have consumption. In speaking of robust girls, I did not intend it to apply to such cases as these at all, but to women who were perfectly and exceptionally well.

DR. F. H. DAVENPORT, read a paper on

#### SOME FORMS OF AMENORRHEA, AND THE TREATMENT.<sup>2</sup>

A NEW INTERPRETATION. — An English quack was recently brought before the police court for practising without due qualification, who, in defending the use of the characters M.D. and F.R.S. after his name, said they meant "money down" and "Fosterer of Real Science." The individual's genius, however, did not save him, for he was fined twenty pounds M.D. — *Journal of American Medical Association.*

<sup>2</sup> See page 389 of the Journal.

THE BOSTON

**Medical and Surgical Journal.**

THURSDAY, APRIL 16, 1891.

*A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.***SUBSCRIPTION TERMS:** \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.*All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.**All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.**Remittances should be made by money-order, draft or registered letter, payable to*DAMRELL & UPHAM,  
283 WASHINGTON STREET, BOSTON, MASS.**THE USE AND THE NEGLECT OF BLOOD-LETTING.**

If blood-letting has gone out of vogue, it is owing to the prevalence of sounder views as to the nature of disease, and the uselessness, the folly and danger of such a remedy. It cannot be said that the greater part of the reasons which our forefathers alleged for their copious blood-lettings were anything but puerile (as was shown by Bennett more than forty years ago), and the prostration and anæmia which were a natural result, the tedious convalescence and often the fatty transformations, were evils which might well offset any temporary benefit.

The general neglect of venesection at the present day is a startling fact as contrasted with the practice of a by-gone age, and hundreds of physicians who have been in active practice for twenty or more years, have never bled a patient. It is not an infrequent event to hear junior members of medical societies boast their incompetency to perform bleeding at the bend of the elbow.

Older practitioners, imbued with the really practical natures acquired in their younger days, do not hesitate on rare occasions to use the lancet in the congestive period of internal inflammations, and when, especially in acute or passive pulmonary congestions, there is a pressing indication to relieve the engorged and struggling heart. At a late meeting of the Royal Medical and Chirurgical Society of London, Dr. Pye-Smith read a paper on the "Therapeutical Value of Venesection, its Indications and its Limits," and gave notes of fifty cases in which bleeding from the arm had been practised. The patients were suffering from bronchitis, acute and chronic broncho-pneumonia, lobar pneumonia, miliary tuberculosis of the lungs, valvular disease of the heart and pericarditis, Bright's disease, aneurism, apoplexy and epilepsy. The remedy was considered, not as one adapted to any single disease, but as useful in meeting certain indications of pathological states. These indications were stated as follows: First, cyanosis, with distension of the right side of the

heart, whether from pulmonary or some other obstruction to the circulation; secondly, the intense pain and dyspnoea of thoracic aneurism; and, thirdly, uræmic and prolonged epileptic convulsions. The use of venesection in the first of these conditions especially commended itself to Dr. Stephen Mackenzie. When the patient was in great peril, with blue lips and a feeble, slow pulse, venesection did great good. In capillary bronchitis, it gave relief and was sometimes curative; but it was in pneumonia that it often gave its best result. He had known life to be saved in cases of hæmoptysis in which cyanosis had been induced by blood running down into the bronchi; on venesection, hæmoptysis ceased and recovery ensued. The indications for its use might generally be stated to be venous congestion with a struggling right ventricle. In uræmia the results were not so satisfactory.

Dr. Broadbent said that he had been brought up in a school that condemned venesection, a position confirmed by the results that he used to see in Paris in cases of rheumatic fever, pneumonia, and other acute conditions. As an independent physician, its proper use had by degrees become apparent to him. In the three categories mentioned by Dr. Pye-Smith, he had employed the method. In aneurism, he agreed with Dr. Stephen Mackenzie that its use would be very rarely needed, if iodide of potassium were freely given. In cases of over-distension of the right ventricle of the heart, his experience differed from Dr. Pye-Smith's and Dr. Mackenzie's, in that he had had better results in cases of mitral valve disease, particularly in mitral stenosis, than in cases of bronchitis. In the latter disease he relied more on the use of emetics. With an overloaded right heart, the indication for venesection, was forcible cardiac impulse, with a small, almost imperceptible, irregular pulse. The forcible impulse showed the power of the heart's action, and that it was in a position to benefit by the relief given by venesection. In pneumonia, the opportunity of benefiting by venesection came quite early. His experience of venesection in uræmic convulsions had been uniformly favorable. The convulsions were not, he believed, directly due to the toxic action on the brain, but only indirectly through the high arterial tension produced by the poison, and then venesection acted in the same way as in over-distension of the right side of the heart. He recalled a case in which convulsions from high tension without uræmic poisoning, were relieved by the abstraction of blood, ten or twelve years ago, and the patient had never since had evidence of kidney disease. In cases of cerebral apoplexy, he felt that the opportunity for employing venesection would be in early ingravescens hæmorrhages.

It will be seen that there was not perfect agreement in the discussion as to the utility of blood-letting in uræmic convulsions, nor is there such agreement in the profession generally, there being, probably, as many good authorities who have discarded the lancet in eclampsia as have still clung to phlebotomy in this affection. These patients are often too anæmic, debil-

itated, neurasthenic to make bleeding warranted; the percentage of robust, plethoric cases with sharp, bounding pulse, high arterial tension and apoplectic tendencies is surprisingly small. Besides, with anesthetics, chloral, and free purgation, puerperal convulsions are generally controlled if any treatment be availing. It is, moreover, maintained that chloroform if pushed to complete anesthesia, has much the same effect on the circulation and sensory, vaso-motor and muscular innervation as is claimed for bleeding. After a brief period of excitement, the subject falls into a state of collapse, and the higher automatic and cortical centres no longer are responsive to stimuli; the muscles before in a state of spasm enter into resolution. The argument that bleeding removes some portion of the pernicious substances which poison the blood, can have little weight when it is considered that the whole remaining mass is as much contaminated as before; another argument often alleged that, by bleeding, the absorption of serous exudates is favored, certainly seems more plausible. The advocates of free bleeding in eclampsia are apt to overlook the fact that if bleeding "may render the spinal bulb anæmic and deaden reflex irritability" (Depaul) it may also when carried beyond certain limits "become itself a cause of irritation to the brain and cord, as is the case after profuse hæmorrhages, of which the final symptoms are almost always convulsive" (Charpentier).

In the cardio-pulmonary conditions of which Drs. Pye-Smith and Mackenzie spoke at the medical meeting, there can be little doubt that immediate, though seldom, probably, permanent benefit may be obtained. These eminent clinical authorities would never bleed as a routine measure, and they would have us keep clearly in view the prominent indication, namely, venous congestion, amounting, it may be to cyanosis, with a struggling right heart. The ordinary practitioner, it must be admitted, seldom sees such cases where he really dares to bleed, fearing lest the bleeding should give his patient the *coup de grace*.

At a meeting of the New York State Medical Association held October 24, 1890, Dr. Homer O. Jewett somewhat severely arraigned the profession for the present neglect of blood-letting. This radical change in the practice of medicine, he says, "has not been wholly in response to the dictates of science, but rather in obedience to a tendency on the part of mankind (that is, physicians), to swing from one extreme to another" (*sic*).

We are sorry that this writer has such a poor opinion of the intelligence of the medical profession, and of the motives and reasons which influence the major part of his colleagues who, it seems, vibrate back and forth perpetually like a pendulum!

If ever a radical change did come about "in response to the dictates of science" it was this; and what is a little remarkable is that the distrust in, and abandonment of blood-letting, began and has continued in all parts of the civilized world simultaneously and in connection with the great scientific development of this century, and as a part of the progress which has at-

tended all departments of medical science. If blood-letting was a "fashion," it was one which had the tradition of ages in its favor and the authority of very eminent men, and if it has been in large part superseded by other methods of treatment, this has been the consequence, not of caprice or "change of fashion" as some pretend, but of a mighty intellectual movement. As far as venesection can be made to appear a rational mode of treatment, so far only will it retain a place in the therapeutics of the future.

#### ARSENIC IN THE MASSACHUSETTS LEGISLATURE.

We publish in another column the majority and minority reports of the Committee on Public Health of the Massachusetts Legislature, with the drafts of the proposed bills accompanying each report. Both bills have the merit of simplicity, but that seems to be the only merit attaching to the bill reported by the majority.

There is no need to forecast the probable action of the Legislature in the premises, but the course of the proceedings thus far plainly illustrates the wisdom of those most familiar with this subject in the past, who advised a delay in action until still further evidence of a positive character had been accumulated. The influence of New York manufacturers, supported by the hired evidence of a chemist brought on from that city, seems to have been as effective as in the past.

Even without legislation against arsenic, the quickening of public sentiment will probably not be without its good results in regard to fabrics, as it has already exercised a control upon wall-papers.

#### MEDICAL NOTES.

**FIRST MOHAMMEDAN FEMALE PHYSICIAN.**—The first Mohammedan woman who has joined the ranks of the medical profession is said to be Katlo Jaroff-Hannum, a native of the Crimea, who has just taken her doctor's degree in the University of Odessa.

**A NEW QUARTERLY.**—Beginning with the April issue the J. B. Lippincott Company will publish quarterly a work entitled "International Clinics." It is intended to collect practical clinical lectures on different subjects, connected with the different branches of medicine, delivered in the leading medical colleges of this country, Canada and Great Britain.

**INFLUENZA IN JAPAN.**—The *Sei-i-kwai Medical Journal* reports that in Tokyo, in January, cases of influenza became much increased and malignant in nature, too. In Shiba (a ward of the city) from January 6th to February 2d, 120 deaths occurred from influenza, among which 216 were men, 204 women, and more than a half of the whole were patients over sixty years of age. In Nihon-bashi (ward), during the last year, the average number of deaths in a month was

240, but since January, it became much increased and about 14 to 15 deaths per day; from January 1st to 31st, there were 381 deaths, and from February 1st to 4th, 41 deaths took place.

A NOVEL MODE OF CONTRACTING SYPHILIS is quoted in the *Lancet*. At the last meeting of the Société de Dermatologie et de Syphiligraphie, M. Feulard reported the case of a man who, having been treated at St. Louis Hospital for post-scabious eczema, principally of the arms, sought re-admission for syphilitic roseola. Researches made as to the seat of inoculation of the virus, revealed an enlargement of the epitrochlear gland, and hard chancres of the posterior surface of the right forearm, of the elbow of the same side, and of the left elbow, the genital organs being free from all sores. It was remarked that the chancres corresponded with the points which would touch a table when, the arms being folded, it served as a *point d'appui* for those members. It is consequently surmised that the raw eczematous surfaces on the backs of the arms became inoculated by contact with an infected table in the ward. M. Besnier remarked that instances of the contraction of syphilis in the wards of an hospital were extremely rare, it being probable that the activity of the virus deposited on instruments, furniture, etc., is only of limited duration. The only exception is the frequent transmission of the disease by means of the Eustachian catheter. M. Lailler cited a case where syphilitic infection occurred at a hospital through a vaginal canula in indiscriminate use for all the patients.

DR. VON GOSSLER has recently resigned his post as Prussian Minister of Religion, Education and Medical affairs. The *Lancet* says that of the services rendered by him to medical science, one of the most memorable was his speech on vivisection in 1883. Another was his energetic defense of vaccination against repeated Parliamentary attacks. He was also a most liberal promoter of the new sciences of hygiene and bacteriology, and the enthusiasm with which he welcomed and promoted Koch's last discovery is still in lively remembrance. The success of the Berlin Congress of Naturalists and Physicians in 1886, and of the Tenth International Medical Congress last August was largely due to him, and it was in recognition of the latter of these services that the Berlin Medical Society created him "honorary member." He was the founder of the "Klinische Jahrbuch" (Clinical Annual), in which the heads of the university clinics have to render annual account of their stewardship, and to discuss medical questions of general importance.

FRAU GELLY.—In speaking of the famous Frau derful woman has, for something like a score of years, Gelly, of Vienna, the *Medical Press* says that this wondrous woman on her own person the wonders of laryngoscopy. She allows her vocal cords to be painted with brushes; submits herself to intubation, also to the extraction of beads, bones, and other foreign bodies which she allows to fall into her larynx, the sinus pyriformis, etc., so

that skill is acquired in these delicate operations. Also posterior rhinoscopy, and passing of catheters into the Eustachian tubes can be learnt with and on her. For all these operations to which she will submit in the course of a lesson she receives the sum of a florin, and will go from the rooms of one student into those of another. It may confidently be asserted that this extraordinary woman has done more good in this world by the practical teaching of several generations of medical men than the writers of many books together. A man who has never seen the laryngoscope, will learn from her in a short time what he could not learn elsewhere, and knowing his way he can at once profit by joining one of the many courses. This same Frau Gelly lent herself during the last congress at Berlin, her stomach being illuminated with an electric apparatus. Professor Oser, in a private course on the modern treatment of stomach complaints has also employed her to demonstrate lavage, etc. She has also shown her bladder with the electric *endoscope*. The greatest admiration and gratitude ought to be entertained by the student of medicine towards this humble and useful worker.

#### BOSTON AND NEW ENGLAND.

CHARGES AGAINST THE MILK-INSPECTOR. — Dr. Charles Harrington of Boston, Inspector of Milk and Vinegar, is subjected to the annoyance of defending himself against an apparently absurdly flimsy charge of neglect of duty.

WATERING THE STREETS. — The mayor of Boston has transmitted a message to the Common Council announcing that the act authorizing cities to water the streets and charge the expense in whole or in part to the abutters, has become a law, and suggesting immediate consideration of the matter. It was ordered that a joint special committee be appointed to consider the matter of the watering of the streets of the city as authorized by the recent act of the Legislature. The Chair appointed as the committee Messrs. Allen, McCellan, Lyons, Lowell and Barry.

THE MEDICAL REGISTRATION BILL, published on page 347 of the JOURNAL of April 2d, after being a second time reported to the House, has failed to pass that body. The opposition to the bill was based partly on the feeling which had been apparently fomented, that the bill would be in some way of advantage to the Harvard Medical School.

ALCOHOL IN CANDY. — The Committee on Public Health, reported the following bill to the Massachusetts Senate:

"No person shall sell to a child under sixteen years any candy or other article enclosing liquid or syrup containing more than one per centum alcohol, unless authorized under the provisions of Chapter 100 of the Public Statutes, and the acts in amendment thereof."

#### NEW YORK.

THREE CASES OF TYPHUS FEVER, two of which proved fatal, have recently developed in New York; the first that have been reported in the city for a con-

siderable time. A case has also come to light at Elizabeth, N. J., and it has now been definitely ascertained that in all these four cases the patients recently arrived from Hamburg, where the disease was no doubt contracted in the filthy sailors' or emigrants' boarding-houses, for which that city is notorious.

**YELLOW FEVER.**—The British steamship *Dryden*, which arrived on April 8th from Rio Janeiro, lost three of her crew from yellow fever during the voyage; two seamen dying on March 18th, and one on March 21st. The vessel left Rio Janeiro where this disease is reported as prevalent, on March 11th. When she arrived in port no other cases of fever were found among the crew, but she was placed in quarantine and a strict surveillance kept over the sailors. There were no passengers on board.

**INFLUENZA** still prevails to a considerable extent, and the death-rate of the city has been unusually high during the past week. On April 7th the mortality from all causes was 195, on the 8th, 178, and on the 9th, 206.

**REJECTED IMMIGRANTS.**—The officers of two steamships which recently brought in immigrants from Italy who were rejected on account of disease, in accordance with the new law, having permitted a number of the rejected individuals to escape before the vessels sailed on the return voyage, the United States District Attorney has been asked by the Superintendent of Immigration, acting under instructions from the Government at Washington, to at once bring action against the agents of the steamship lines thus violating the law.

**THE DA COSTA LABORATORY OF BIOLOGY.**—At a meeting of the Trustees of Columbia College held April 6th, it was determined to use the bequest of \$100,000 from the late Charles M. Da Costa as the foundation endowment of a department of biology, to be known as the Da Costa Laboratory of Biology. It was also decided to accede to the request of the Faculty of the Medical Department, and erect the biological laboratory on land brought to the college through the union with the College of Physicians and Surgeons; and it was proposed that the head of this department be known as the Da Costa Professor of Biology. It is the intention to afford as complete opportunity for biological research as can be had anywhere in the country, and it is hoped that the laboratory can be opened in October, 1892.

### Miscellany.

#### LEGISLATION ON ARSENIC IN MASSACHUSETTS.

A MAJORITY of the Committee on Public Health have reported the following bill to the Massachusetts Senate. As will be seen such legislation would amount practically to nothing at all.

**SECTION 1.** Whoever by himself, or by his servant or agent, or as the servant or agent of any other person, manufactures, sells or exchanges, or has in his custody or possession with intent to sell or exchange, or exposes or offers for sale or exchange, any children's toys or confectionery containing or coated wholly or in part with arsenic, shall be punished by a fine of not less than \$50 nor more than \$100.

**SECT. 2.** The State Board of Health may make such investigations and inquiries as they deem necessary as to the existence of arsenic in any paper, fabric or other article offered for sale or exchange, and for that purpose may appoint inspectors and chemists and expend an amount not exceeding \$1,000, and report to the next Legislature by February 1, 1892.

**SECT. 3.** Every person offering or exposing for sale or exchange any paper, fabric or other article shall furnish a sample thereof sufficient for the purpose of analysis, where such sample can be obtained without damage to the remaining portion, to inspector, chemist or other agent or officer employed by the State Board of Health, who shall apply to him therefor for that purpose, and who shall tender him the value of the same. Whoever violates the provision of this section shall be punished as provided in section one of this act.

A minority of the committee, consisting of Messrs. Harriman, Hodges, and Frazer, dissented, and sent in the following report:

"The undersigned respectfully dissent from the report of their associates, and recommend the annexed amendments of Chapter 263 of the Acts of 1882. While to the portions contained in the bill reported, the undersigned cordially assent, as recognizing the danger against which they desire to protect the community; and consider included in these amendments.

"The petitioners 2,352 in number, of whom 1,207 are physicians (including a large majority of the leading members of the profession in Massachusetts) ask for the same protection against the use of dangerous substances in papers, fabrics, etc., as that now afforded by legislation against the adulteration of drugs, food, milk, vinegar, etc., a protection similar to that afforded in Sweden, Germany, Austria, Russia, Bavaria, Denmark, Holland and other countries by legal enactments.

"No remonstrance, except the number of dealers in wall-papers (mostly from New York), and an export (also from New York) employed by them, and his former associate or subordinate, and one gentleman interested in apartment houses where the papers were complained of, has appeared before the committee in person or by written communication. Not a single other citizen, manufacturer, expert or physician has appeared before this committee in any form to object to the passage of such a bill, and not a single individual appeared to object to the limitation of the use of arsenic in fabrics. The largest manufacturer of textile fabrics in Massachusetts or New England, speaking for other large manufacturers also did not only not object to such a bill to control the 250,000,000 of yards for the manufacturers of which he spoke, but stated 'we would be glad to have a reasonable and fair law which should prohibit the use of arsenic by any mills inside the State.' He also stated 'the textile manufacturers of Massachusetts will not oppose a proper law, but will work under it.'

"The only questions before the committee were:

- (1) Whether arsenic in fabrics or wall paper is shown to be a source of danger to health; (2) whether it could be prevented or mitigated by legislation; and (3) whether the inconvenience or expense to the dealers who profit by permitting its use, was a reasonable ground for refusing relief. As before stated, not a single physician, except one from New York, before referred to as the associate or subordinate of the expert employed, appeared to deny it.

"(1) A number of leading physicians testified to their experience of cases of arsenical poisoning from paper and fabrics. Individuals narrated the sufferings of themselves or of members of their families. Evidence of foreign physicians, and the action of foreign governments, supported and confirmed this position.

"The facts showing that illness results from exposure to arsenic in papers and fabrics, and other articles of domestic use, are too striking, too well attested, and too serious to be dismissed with ridicule. The following cases, taken from documents cited at the hearings, tell their own story: (a) From the *London Sanitary Record*, 1879. A father, mother and four children inhabit a room recently papered with an arsenical paper. Very soon all complain of great soreness of the eyes and nose, headache, thirst, sore throat, and pains in the abdomen. The sore throat increases and leads to ulceration, and at the end of four months the four children are dead. (b) *Ibid.* An infant sucks a piece of green paper, such as is to be bought in the kindergarten shops of this city, and is even to be found on our walls, and dies in twenty-four hours from arsenical poisoning. (c) A physician reported at one of the recent hearings, the case of an outbreak of sickness among the children at an infant asylum near Boston, which he traced to arsenical dresses just put on by the nurses. Two of these children died and the nurses were affected in various ways. (d) Another infant under the same physician's care had a typical form of arsenical paralysis, from which it barely recovered. (e) The case of a man was reported who was recently at the Massachusetts General Hospital for typical arsenical paralysis, which deprived his family for months of his support. (f) From the Massachusetts State Board of Health, 1883. A London surgeon lost two children from inflammation of the bowels which he traced to arsenical wall-paper.

"It is a grave responsibility to assume in the face of this evidence, that the danger is wholly imaginary.

"How many more cases shall be allowed to accumulate to save loss of profits for dealers?

"If the danger exists at all it must be widespread, for the exposure is widespread. It is not every one that falls a victim, but it is the weak, the infants, the predisposed; and the disbelief of those that remain unaffected, increases the danger of the rest.

"(2) Some dealers declare that their papers are substantially free from arsenic, and there can therefore be no difficulty in excluding it to this extent. Chemists declare that it is perfectly practicable, nor can paper-dealers be allowed to save a few cents per roll by poisoning the community any more than grocers or druggists.

"The undersigned, therefore, recommend the following amendments to the bill reported by the committee, on the same line with the existing law, as to the adulteration of drugs and food, adding to the articles prohibited by the reported bill, others which the evidence shows often contain arsenic."

PUB. STAT., 1882, Chap. 263, Sect. 1.

No person shall, within this Commonwealth, manufacture for sale, offer for sale, or sell any drug or article of food, or of household or domestic use, which is adulterated within the meaning of this act.

In Article 3, end of (b), after "consuming it," insert (8): In the case of articles for household or domestic use, if the same contain arsenic or any other poisonous ingredient which may render them injurious to the health of a person using them.

## TUBERCULOSIS OF CATTLE IN NEW YORK.

At a meeting of the Board of Health held April 7th, a report was received from the veterinarian of the Department, Dr. S. K. Johnson, in which he stated that on April 1st he inspected sixty-four head of cattle, belonging to a single owner, at Carmel, Putnam County, and found that almost all the cattle were affected with a cough, and that the temperature of many was from  $102^{\circ}$  to  $103\frac{1}{2}^{\circ}$ . Upon a more careful examination he ascertained that twelve heifers and four cows were suffering from tuberculosis, and it was his opinion that almost the entire herd was suspicious, and a proper subject for observation. He made post-mortem examinations of two cows. In one, a two-year old, he found the lungs almost an entire mass of tubercles, and all the other internal organs affected. In the case of the other, a five-year old cow, the lungs only were tuberculous. In consequence of this report, the Board adopted a resolution requesting the Mayor to call the attention of the Governors of New York, New Jersey and Connecticut to the danger to the public health involved in such a condition of affairs.

The Secretary of the Board, Col. Clark, also wrote a letter to the Secretary of the State Board of Health, Dr. Lewis Balch, calling his attention to the facts set forth in Dr. Johnson's report, and adding: "The Commissioners are informed that the milk from the farm referred to is sold to a company engaged in condensing milk, and that it is possible that diseased cattle may be sold from this farm to other parts of the country. The Board respectfully calls your attention to the danger to the public health, as well as to farming interests generally, from the prevalence of tuberculosis, and to the existence of the disease in the place above named and possibly in other localities." As a result, the local Board of Health at Carmel has been urged by the State Board to take immediate steps to prevent the sale of milk from the infected herd.

## THE "VIRILE REFLEX."

Dr. C. H. HUGHES has described, under the name "Virile Reflex," a phenomenon which he finds present in all healthy men. He begins by putting the person on his back, making the skin of the penis tense by clapping the prepuce near the frenum with the left thumb and index finger, and drawing it firmly towards the umbilicus, the remaining digits of that hand being placed low down on the dorsum of the organ for perceptive purposes. The side or dorsum of the penis near the perineal extremity is then sharply percussed, which, in the normal state, causes a quick and very perceptible retraction of the bulbo-cavernosus portion. This "penis percussion reflex" is feeble or absent in children under the age of puberty; it becomes impaired or abolished after prolonged excessive venery. It is not impaired in masturbation when the habit has not destroyed the sexual power, but excessive onanism, long continued and accompanied by neurasthenia, diminishes the reflex. In old men who have lost virility the sign is absent. It does not always run *pari passu* with the other reflexes in disease of the lumbodorsal cord, though in a case of transverse dorsal myelitis, with double ankle clonus, the author could elicit "a kind of erector penis clonus," as long

<sup>1</sup> *Alienist and Neurologist*, January, 1891.

as the foot clonus was obtainable. From his experience the matter, the author judges that it appears worthy to rank with any of the hitherto recognized diagnostic reflexes.

#### AN ALKALOID DERIVED FROM TUBERCLE BACILLI.

ZUELZER<sup>1</sup> has obtained an alkaloid from tubercle bacilli in the following manner: The whole contents of the tube holding the bacillary growth were repeatedly extracted with hot water acidulated with hydrochloric acid, filtered, evaporated down, and repeatedly precipitated with platinum chloride; the double salt was then split up by H<sub>2</sub>S, filtered and dried. An almost white, well-crystallized salt was thus obtained, easily soluble in hot water. This hydrochloride caused, when subcutaneously introduced into rabbits and guinea-pigs, the following characteristic toxic symptoms: one centigramme increased the frequency of respiration within five minutes to 180 in the minute. This effect lasted about a quarter of an hour. At the same time, the rectal temperature rose from 38° to 10° C. in two out of ten experiments; in the rest from half to one degree. The bulb of the eye showed a remarkable protrusion; the eyes were very lustrous, the pupils somewhat dilated, and there was slight congestion. The protrusion was greater on the side of the injection. Only three rabbits died; they had received between two and three centigrammes, and died within four days. There was redness and extravasation at the site of injection; also small hemorrhages in the stomach.

#### THE ACTION OF PRUSSIC ACID IN TUBERCULOSIS OF THE LUNG.

KORITSCHNER<sup>2</sup> reports his investigations on this subject. Inaugurated in medicine by the Italian physicians, Brera, Borda, Brugnatelli and Rasori, prussic acid was employed at the beginning of the century against every disease, with great results. The most incredible effects were attributed to its healing action; even tubercular cavities were healed by its administration. Rapidly, however, its pan-therapeutic virtues shrank, until now its preparations are used for stomachic cramps and palpitation, and occasionally as a specific against tuberculosis of the lung.

Koritschner resolved to try its efficiency in pulmonary tuberculosis, giving inhalations of the acid in vapor form, made by the action of potassium cyanide and dilute sulphuric acid. Thirty patients with incipient pulmonary phthisis were placed in a chamber two hours every morning and afternoon for six weeks; in this room the fumes were driven, no other treatment being added. The conclusions reached were as follows: Chronic prussic acid poisoning was produced in seven patients; diminution of cough and liquefaction of sputa occurred in all; reduction of pulse and respiration rate occurred in every case; doubtful action on body weight, night sweats and fever were observed; while there was absolutely no effect on the tubercular process in any way, which increased regularly and steadily throughout the treatment. Realizing the

dangers of the treatment, Koritschner wisely concludes that the results were too small to justify its use in such cases. He believes its reputation is due in phthisical conditions to its sedative action on the cough.

#### THE TRANSPLANTATION AND GROWTH OF MAMMALIAN OVA WITHIN A UTERINE FOSTER-MOTHER.<sup>1</sup>

In the *Proceedings of the Royal Society*, published January 17, 1891, there is a very interesting account of some experiments made by Mr. Walter Heape, showing that it is possible to make use of the uterus of one variety of rabbit as a medium for the growth and complete foetal development of fertilized ova of another variety of rabbit. Two ova, just undergoing segmentation, were obtained from an Angora doe rabbit that had been fertilized by an Angora buck thirty-two hours previously. These were immediately transferred into the upper end of the Fallopian tube of a Belgian hare doe that had been fertilized three hours before by a buck of that breed. She was a seven-months-old virgin doe, and in due course of time after the covering gave birth to six young; four of these resembled herself and her mate, while two showed undoubted Angora characteristics in the long, silky hair peculiar to that breed, in being albinos, and in a habit, also peculiar to Angoras, of slowly swaying their head from side to side as they look at a person. All the young at birth had some skin disease that disappeared under treatment, and one of the Angora young was scantily supplied with hair. Both the Angora young were bigger and stronger when born than the others, three of the Belgian hare young dying when they were some three months old. Each variety seemed to be *sui generis*. These experiments were undertaken to determine whether a uterine foster-mother would have any influence upon the foster-children, and whether the presence and development of foreign ova in the uterus of a mother would affect the contemporary offspring of that mother.

#### RETINOL.

RETINOL, sometimes erroneously known as resinol, was discovered in 1838, but was little used in medicine until last year, when attention was again called to it.<sup>2</sup> It is made from resin, and is a liquid with a density of 0.9. It is either brown or yellow according to the purity of the resin; the later being the better preparation. It looks something like olive oil, has a slightly acid reaction and has a slight odor of fir.

Vigier speaks highly of retinol as a dissolvent for many active substances.<sup>3</sup> Being antiseptic, non-irritant and incapable of alteration even on exposure to air, it has the special advantage of dissolving a large number of antiseptic bodies and other agents employed in practical medicine. Combinations can be prepared in the form of ointments, capsules or solutions. Salol is soluble in ten parts of retinol; iodol, naphthol, and aristol in fifty parts, camphor in twenty, ephrasiophanic acid in forty, cocaine in thirty, and strychnine in forty. Camphorated naphthol is very soluble in this substance.

<sup>1</sup> *Lancet*, Medical Recorder, February 25th.

<sup>2</sup> *Lancet*, Medical Magazine, from Wiener klin. Woch., January 12th.

<sup>3</sup> *New York Medical Journal*, February 28th.

<sup>2</sup> *La Medicine Moderne*, February 12th.

<sup>3</sup> *Bull. et Mem.*, February 1st.

Oil of Cade mixes with it in any proportion, and also phenic acid, essence of terebinthine, alcohol and ether. Resorcin is dissolved first in a small quantity of glycerine before the retinol is added, and Iodoform must first be treated similarly with ether. Iodine is also soluble in retinol, but a resinous substance is shortly deposited. Retinol combines readily with fatty matter, with oil, vaseline, ointments, lanoline, oleonaphthine and glycerine, even replacing the latter at times with advantage as an antiseptic, except where greater consistency or the presence of glycerine is required.

### PRESCRIPTIONS.

**SYCOSIS VULGARIS.** — Rosenthal<sup>1</sup> has employed the following paste with success:

R Acid tannic	. . . . .	3 i.
Sulph. præcip.	. . . . .	3 i.
Zinc oxide	. . . . .	3 iiss.
Amyl	. . . . .	3 x.
Petrolati	. . . . .	M.

This is applied morning and evening, gauze being placed above the dressing. Epilation is said to be unnecessary by this treatment.

**VOMITING OF PREGNANCY.**<sup>2</sup> — The *Deutsche medicinische Wochenschrift* recommends the following treatment for vomiting of pregnancy:

R Creasote	. . . . .	10 drops.
Acetic acid	. . . . .	20 drops.
Sulphate of morphine	. . . . .	1 grain.
Distilled water	. . . . .	1 ounce. M.

A small teaspoonful every half-hour until four doses have been taken.

In a case of vomiting of pregnancy in a phthisical patient, Kaatzer<sup>3</sup> obtained immediate and permanent effect with the following:

R Creasoti	. . . . .	m xxx.
Alcohol	. . . . .	3 i.
Tinct. gentian	. . . . .	3 iiss.
Ext. coffee	. . . . .	3 iiii. M.
Aque	. . . . .	3 iiii. M.

Sig. To be shaken. One teaspoonful two or three times a day in milk.

### ICHTHYOL IN ACNE.<sup>4</sup>

R Ichthyol	. . . . .	grs. xlv.
Distilled water	. . . . .	3 iiss.
Glycerin	. . . . .	3 ij.
Dextrin	. . . . .	3 iiss. M.

Mix by the aid of gentle warmth.

Paint in the evening; wash with warm soap-water in the morning; during the day paint with a weak solution of corrosive sublimate.

**RHUBARB IN THE TREATMENT OF OXYURIS VERMICULARIS.** — Sidney Martin,<sup>5</sup> in a large number of observations, has seen good results after the employment of small doses of rhubarb. The drug appears to regulate the movements of the intestines, and this action is so pronounced that it has been unnecessary to apply any injections. He advises the following formula:

R Tincture of rhubarb	. . . . .	20 drops
Carbonate of magnesium	. . . . .	3 grains.
Tincture of ginger	. . . . .	1 drop.
Water	. . . . .	3 drachms. M.

This mixture to be given three or four times a day, according to the effects produced in the intestines.

### METEOROLOGICAL RECORD.

For the week ending April 4, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Date.	Barometer. Daily mean.	Thermometer. Daily mean. Maximum. Minimum.	Relative humidity. 8.00 P. M.	Direction of wind. 8.00 A. M.	Velocity of wind. 8.00 P. M.	Wet'r. 8.00 A. M. 8.00 P. M.	Rainfall in inches.
S. . . 29	29.91	42 47 36	92	65 78	N. N.W.	12 7	O. F.
M. . . 30	30.12	41 45 26	52	53 52	N.W. E.	12 6	C. C.

Hyde Park	10,193	—	—	—	—	—	—	—
Peabody	10,158	—	—	—	—	—	—	—

Deaths reported 3,854; under five years of age 1,340; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrheal diseases, whooping-cough, erysipelas and fevers) 419, acute lung diseases 1,008, consumption 415, diphtheria and croup 147, typhoid fever 87, scarlet fever 57, diarrheal diseases 47, whooping-cough 28, cerebro-spinal meningitis 19, erysipelas 13, malarial fever 6.

From diarrheal diseases New York 19, Chicago 11, Brooklyn 7, Philadelphia 6, Boston, Cincinnati, Nashville and Lowell 1 each. From whooping-cough New York 13, Brooklyn 6, Chicago 4, Philadelphia 2, Washington, Nashville and Springfield 1 each. From cerebro-spinal meningitis Brooklyn 6, New York 5, Chicago 4, Washington 3, Boston 1. From erysipelas New York 5, Chicago and Washington 3 each, Brooklyn and Boston 1 each. From malarial fever New York 3, Brooklyn 2, Philadelphia 1.

In the twenty-eight greater towns of England and Wales with an estimated population of 10,010,426, for the week ending

<sup>1</sup> Annales de Derm. et de Syph., No. 4, 1890.

<sup>2</sup> Medical News, April 11th.

<sup>3</sup> Sentinel Med., No. 1, 1891.

<sup>4</sup> Merck's Bulletin.

<sup>5</sup> Univ. Med. Mag., from Gaz. hebdomadaire des Sci. Med. de Montpellier, January 10th.

March 28th, the death-rate was 21.2. Deaths reported 4,074: acute diseases of the respiratory organs (London) 466, measles 150, whooping-cough 134, diphtheria 33, diarrhoea 35, fever 30, scarlet fever 20.

The death-rates ranged from 14.1 in Derby to 34.6 in Huddersfield. Birmingham 19.7, Bradford 20.1, Hull 23.0, Leeds 22.7, Leicester 21.7, Liverpool 23.5, London 19.3, Manchester 25.9, Newcastle-on-Tyne 24.6, Sheffield 21.1.

In Edinburgh 25.7, Glasgow 32.9, Dublin 29.1.

#### OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM APRIL 4, 1891, TO APRIL 10, 1891.

By direction of the Acting Secretary of War, Captain JNO. VAN R. HOFF, assistant surgeon, now in New York City on leave of absence, is assigned to duty as an additional member of the Board of Medical Officers, constituted by paragraph 18, Special Orders 52, March 7, 1891, from this office, to meet in New York City, for the examination of candidates for admission to the Medical Corps of the Army, etc. S. O. 78, Par. 6, A. G. O., Washington, April 7, 1891.

#### OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE, FOR THE THREE WEEKS ENDING APRIL 4, 1891.

WYMAN, WALTER, surgeon. To inspect Delaware Breakwater Quarantine Station. March 27, 1891.

PREVANCE, GEORGE, surgeon. Detailed as chairman Board of Examiners. April 3, 1891.

SAWTELE, H. W., surgeon. To proceed to Rockland, Me., on special duty. March 23, 1891.

GASSAWAY, J. M., surgeon. Granted leave of absence for five days. April 2, 1891.

GODFREY, JOHN, surgeon. Detailed as member Board of Examiners. April 3, 1891.

IRWIN, FAIRFAX, surgeon. Detailed as recorder Board of Examiners. April 3, 1891.

PECKHAM, C. T., passed assistant surgeon. Granted leave of absence for ten days. March 26, 1891.

WANDIN, EUGENE, passed assistant surgeon. Granted leave of absence for thirty days. March 27, 1891.

STIMMONS, W. G., assistant surgeon. To proceed to Charleston, S. C., for temporary duty. March 26, 1891.

#### SOCIETY NOTICES.

SUFFOLK DISTRICT MEDICAL SOCIETY.—The annual meeting will be held at 19 Boylston Place, on Saturday, April 25, 1891, at 8 P. M.

Paper, Dr. E. H. Bradford, "New Methods in Treating Latent Curvature."

Reports of the Treasurer, Librarian, the Committee on Social Meetings and the Nominating Committee. Election of officers. Supper after the meeting. JAMES J. MINOT, Secretary.

AMERICAN ASSOCIATION OF ANTHROPOLOGY AND ZOOLOGY.—The fifth meeting of this Association will take place in Washington, D. C., on September 22-25, 1891, in connection with the Congress of American Physicians and Surgeons. Daily sessions will be held from 9 A. M. to 4 P. M.

Preliminary Programme.—The following papers have been promised: A Review of the Evidence of the Transmission of Syphilis to the Third Generation, by Dr. Abner Post, of Boston; Relation of Syphilis to Stricture of the Rectum, by Dr. E. W. Taylor, of New York; Surgery of the Uterus, by Dr. A. T. Cabot, of Boston; Some Experience with Suprapubic and Perineal Drainage, Temporary and Permanent, in Vesical Disease, by Dr. Edward L. Keyes, of New York; Some Cases Illustrating Urethral Stricture from Unusual Causes, by Dr. Francis S. W. Benson, of Boston; On the Radical Cure of Urethral Stricture by Restoration of the Mucous Membrane to the Normal Condition, by Dr. John P. B. Hayson, of St. Louis; Observations upon the Symplicin Cure, by Dr. J. Blake White, of New York; Microscopic Study of Chronic Non-specific Prostatitis of Sixteen Cases, and a Study of the Pathology of the Prostate Gland, by Dr. George E. Brewer, of New York; New Methods in the Treatment of Urinary Tract Disease, by Dr. E. T. Cabot, of Boston; On the Pathology of the Bladder, by Dr. C. H. Meritt, of London; Short Note on a Case of Urinary Stricture, treated by the (Koch's) Subcutaneous Method, by Dr. J. H. Brown, of New York; On the Use of Salicylic Acid in the Treatment of Certain Forms of Cystitis, by Dr. John P. Brown, of St. Louis; The Dry Poultice in the Treatment of

Epididymitis, by Dr. George E. Brewer, of New York; Exhibition of an Antiseptic Syringe for Hypodermic Medication, by Dr. J. Blake White, of New York; On the Occurrence of Nephritis in Early Syphilis, by Dr. J. A. Fordyce, of New York. J. A. FORDYCE, Secretary.

#### OBITUARY. CARL BRAUN.

Carl Rudolf Braun, Ritter von Fernwald, Professor of Obstetrics and Gynecology in the University of Vienna, etc., died, March 28th, aged sixty-nine years.

Carl Braun graduated in Vienna in 1847, and after a short time spent in the pathological laboratory became assistant in obstetrics under Klein. In 1855 he was called to the Tyrol as professor, where he, in 1857, published his text-book of obstetrics. At about this time, after declining the chair at Zurich and at Pavia, he came back to Vienna, on the death of Klein, as professor of the obstetrical clinic, and at the same time devoted himself to the establishment of a gynecological clinic in connection with the lying-in department. From this time until his death Braun has been one of the most prominent figures in the medical life of Vienna, and in obstetrics has attained a world-wide reputation.

#### DEATHS.

DAVID HUME GORDON, M.D., died in New York April 8th. He was a native of Schenectady. He removed to New York in 1886.

RALPH A. PARSONS, M.D., M.M.S.S., died of diphtheria in West Roxbury, April 4th, aged twenty-nine.

JOSHUA OTIS STANTON, M.D., of Washington, D. C., died suddenly in that city, April 9th, aged fifty-three.

RANSOM DEXTER, M.D., died in Chicago, April 2d.

AN EPIDEMIC OF TYPHOID FEVER IN  
LOWELL, MASS.ABSTRACT OF A REPORT UPON THE SANITARY CON-  
DITION OF THE WATER-SUPPLY MADE TO THE  
LOWELL WATER BOARD, APRIL 10, 1891.BY PROF. W. T. SEDGWICK,  
Massachusetts Institute of Technology, Biologist to the State Board of  
Health of Massachusetts.

**Object and Scope of the Investigation.**—Five Systems of Water-Supply in Lowell. — The Direct Canal Water-Supply in Mills. — Chemical Examinations of the City Water and of the Merrimack River. — Bacteriological Examinations of the City Water and of the Merrimack River. — Investigations of the Reported Cases of Typhoid Fever, with Special Reference to Date, Location, Water-Supply, Milk-Supply, etc. — Typhoid Fever Excessive in Lowell for many Years. — Probable Cause of the Recent Epidemic of Typhoid Fever. — Summary.

## OBJECT AND SCOPE OF THE INVESTIGATION.

The immediate cause of this investigation was a severe epidemic of typhoid fever in Lowell. It will be shown beyond that this city has, for many years, suffered from typhoid fever above any of the cities of Massachusetts with two exceptions, one of which is Lawrence.

The earlier months of 1890 had not shown, in comparison with the same months of the previous year, any unusual prevalence of this disease. June and July showed some increase as compared with the corresponding months of 1889, but August, 1890, was again, not noticeably different from August, 1889.

In September, however, a severe epidemic of typhoid fever began, which steadily increased during October, attained large proportions, and culminated in November, and then gradually declined. The course and severity of this epidemic is shown upon the following comparative table:

## TYPHOID FEVER IN LOWELL.

Deaths and Cases Reported, 1889-90, and 1890-91.

Months.	Deaths.		Cases Reported.		Increase in 1890-91.	
	1889-90	1890-91	1889-90	1890-91	Deaths.	Cases Rep'd.
August.....	5	6	17	15	..	..
September...	7	10	14	27	43%	93%
October.....	3	10	13	69	233%	431%
November....	9	28	21	122	211%	481%
December....	9	25	35	104	178%	137%
January....	5	19	23	67	289%	191%
February....	6	14	29	46	133%	59%
March.....	4	9	17	46	125%	171%
Totals.....	48	121	169	496	152%	193%

The severity of the epidemic is still better shown upon the following table:

## TYPHOID FEVER IN LOWELL.

Date.	Cases Reported.	Deaths.
April, 1889, to March, 1890.....	201	61
April, 1890, to March, 1891.....	511	119
Increase, 1890-91.....	310 (167%)	76 (118%)

This table shows that, while for the year preceding April 1, 1889, the number of cases of typhoid fever reported to the Board of Health was 204, and the number of deaths from the same disease was 64, the number of cases reported for the year following, which includes the period covered by the epidemic, was 541, while the number of deaths was 140. This is an excess for the year including the epidemic, of 340 cases and 76 deaths; an increase of 167 per cent. in the number of typhoid fever cases reported, and of 119 per cent. in the mortality.

It must also be remembered that there are always some cases which are not reported, besides many mild cases which never come to light. I have positive evidence that during the twelve months following April 1, 1890, there have been more than 700 cases of typhoid fever in Lowell, and this fact, taken in connection with the large number of deaths indicates that within that year about one per cent. of the total population has been affected with typhoid fever.

The gravity of the situation does not appear to have been recognized during the height of the epidemic, namely, in November. But when, at length, in December, the fact was realized that there had been during the preceding month 122 cases of typhoid fever reported, and 23 deaths from the same disease, or 101 cases and 19 deaths more than in the same month of the previous year, there was naturally much uneasiness. Suspicion fell upon, among other things, the public water-supply, which is drawn in large part directly from the Merrimack River; whereupon the Water Board ordered an inquiry, and instructed me to make a thorough investigation. By special vote I was authorized to employ all means at my disposal "to ascertain if any danger of any kind existed in the water of the Merrimack River at Lowell." I was also instructed to make, as soon as possible, an exhaustive Report.

During a part of the previous autumn I had been engaged as a representative of the State Board of Health in a sanitary investigation of certain well-waters in Lowell, so that I was already somewhat acquainted with the local conditions, and therefore lost no time in beginning this investigation. The attention of the State Board of Health had also been drawn to the same subject, and I had already been instructed to make an inquiry.

## FIVE SYSTEMS OF WATER-SUPPLY IN LOWELL.

The investigation had hardly begun before I discovered that the problem was unexpectedly complicated by the existence in Lowell of five distinct systems of water-supply, two of which are obviously polluted by sewage within the city itself.

The principal supply is the city water drawn partly from the filter gallery in Pawtucketville, but chiefly, and without any attempt at purification, from the Merrimack River. The water from the river mixes with that from the filter gallery in the gate-house at Pawtucketville, and is afterwards pumped to reservoirs from which it is distributed to all parts of the city.

A second system is that owned by the "Proprietors of Locks and Canals on Merrimack River," and used chiefly for fire purposes and the feeding of boilers. It is also used, however, to a small extent, for drinking-purposes. The supply for this system is drawn from the Merrimack canal through the penstock of the Lowell

machine shop, and is then pumped to a small reservoir on Lynde's Hill, in Belvidere, from which it flows to a few houses, and to most of the mills situated upon the canals fed from the Merrimack River. It will be shown beyond that this water is much polluted. The third system is also supplied by canal water, and although intended chiefly for washing purposes, this water is, in fact, used, to some extent, for drinking. It is still more polluted than the Lynde's Hill supply. The fourth system is the supply derived from wells. Many of the wells that formerly existed in Lowell have been closed or abandoned, but some, often of questionable purity, are still in use. Some of the mills are supplied with well-water, which is usually brought and kept in wooden pails, for drinking purposes. The fifth system is that of the so-called spring waters which are publicly sold for drinking purposes.

#### THE DIRECT CANAL-WATER SUPPLY.

More than one-fourth of the population of Lowell (78,000) is employed in the mills. Their homes are scattered about the city, although many live in the vicinity of the mills or in the so-called "Corporation" boarding houses.

Most of the mills are supplied with drinking-water drawn from wells or from the city supply. In the majority of cases the several rooms of the mills are supplied with drinking-water by means of wooden pails, in which water is brought by hand from some tap of city water, or from some well, either in the mill itself, or in the mill yard, or in the immediate vicinity of the mill. In a few cases only, for example, in the Merrimack Mills, city water is said to have been introduced into every room. In the Hamilton Mills a special tank of large size has been built, into which city water is run. The tank is so large that, in summer, ice, in cakes, is easily introduced at the top. At the bottom of this reservoir is a series of taps to which messengers are sent, when necessary, from the various rooms. These mills, therefore, are provided with an abundance of city water, properly cooled in summer. The Massachusetts Mills have a well, conveniently placed in their spacious yard. The Boott is supplied from wells in the neighborhood. The Lawrence has a similar source of supply. The Tremont and Suffolk obtains its drinking water from a tap on the city service. The Lowell Machine Shop has one city tap, but depends chiefly on a well in the mill yard. The mills on the Concord River canal, also use, in some cases, well waters, supplying the several rooms by pails.

It appears, therefore, that with a few exceptions the mills are usually not piped for city water. There is, nevertheless, in most of the mills in Lowell a complete system of water-supply, although it is not intended to serve for drinking purposes. This is the canal water, which is drawn, by nearly every mill situated upon a canal, directly from the wheel-pit, and pumped to a tank at the top of the mill. From this it flows by gravity to all parts of the mill, supplying, for example, the water for the water-closets, for washing, for atomizing, etc.; in short, for all purposes except for drinking. In many, perhaps in most, of the rooms this water is delivered by faucets, of the ordinary pattern, projecting a foot or two above large sinks. It is generally the most accessible, and sometimes the only easily accessible, water; and this circumstance added to the fact that it is often cooler than the pail water, which has

perhaps been standing for some time in a heated room, tempts the indifferent or careless to use it for drinking. I have abundant evidence that it is often used for drinking, and is sometimes preferred to the pail-water supply. I have myself seen a drinking cup hanging upon a canal-water faucet, and I discovered one overseer who himself so much preferred canal water for drinking that he did not care to have any other water in the rooms under his care. In the statistics of the cases of typhoid fever given beyond, it is shown that some freely admitted that they had frequently drunk canal water. It is also alleged with some show of probability, that the bobbin boys sometimes detailed to keep the pails filled with drinking-water, occasionally, in order to avoid a longer journey, go to another room, and there fill the drinking-water pail with canal water. Again, I have myself sometimes seen drinking-water pails standing entirely empty, apparently from oversight or neglect. These various circumstances prove indubitably that some canal water is used for drinking.

The exact quality of the canal water varies with the situation of the mill. Some of the mills are upon the "upper level," that is, receive canal water from the Pawtucket, Northern, Western, and Merrimack Canals. Others are upon the "lower level," that is, receive canal water which, originally drawn from the Merrimack River, has already passed along the canals just named and through the mills upon the upper level, and is now used over again by mills on a lower level before it finally passes into the river still further down. Some overflow water from the upper canals also feeds the mills on the lower level without having passed through the mills above, but the mills upon the lower level necessarily use mostly, canal water which has already passed through the mills on the upper level.

The sources of pollution of the water of the upper canal (from numerous privies, two city sewers, three overflow sewers, the water-closets of the Lowell Hospital, etc.) have already been described in the previous section. We have only to reflect, first, that all of the mills on the upper level are directly supplied with the water of the upper canal; and second, that the same water, carrying all the sewage from the large mills on the upper level, is similarly used by the mills on the lower level, in order to realize the dangers to which users of this water for drinking, especially on the lower level, are exposed. This is more emphatically the case during an epidemic of typhoid fever in the city, when the germs from many cases, especially mild cases, and cases in the early stages of the disease, beginning with the sewers of Walker and School Streets, adding the discharges from the Lowell Hospital, and from various privies, and, finally, the excreta from thousands of workers in the mills on the upper level, cannot fail to infect the canal water. It must certainly be counted a most fortunate circumstance that this canal water is not more generally used for drinking purposes.

As soon as these facts concerning the use and quality of the canal water were brought to light, I notified the Board of Health, who immediately caused proper placards to be posted in the mills, warning the operatives against the use of canal water for drinking.

The idea naturally suggested itself, that in the use of polluted canal water might lie the principal cause of the epidemic of typhoid fever. In the hope that this would prove to be the case, and that the city

water had been unjustly suspected, I immediately set to work to locate and investigate the cases of typhoid fever, and to determine whether or not the epidemic could be attributed to this source.

Five separate systems of water-supply in Lowell have now been described. With respect to three of these I find no evidence which makes further investigation necessary. The epidemic of typhoid fever in 1890 is not attributable to the Lynde's Hill Reservoir supply, or to the well-water supply, or to the spring-water supply. If caused by drinking-water of any kind, it must have been by canal water or by city water, or by both. We have seen that the canal water is so extensively polluted, as to suggest that the entire epidemic might possibly have sprung from this source. But before examining the evidence bearing upon the canal-water theory, we must turn to a closer examination of the principal supply, the city water.

In the present case, chemical examinations were less necessary than usual, because the fact, and the time, of sewage contamination of the Merrimack River above Lowell are already well-known. Chemical analysis, nevertheless, is highly important even in the present case, since it enables us to measure with much precision the degree of sewage pollution of the river at Lowell, or, in other words, to find the proportion of sewage in the Lowell city water. Fortunately, the State Board of Health has, for four years past, been making monthly chemical examinations of the water of the Merrimack River, over the intake of the Lowell Water Works. The Board has also made a special study of the Merrimack River, in order to determine its precise condition with regard to sewage pollution. As a result of these investigations the Board has estimated that the proportion of sewage that has been directly mingled with the water of the Merrimack River is, at the time when it arrives at Lowell, about one part of sewage in every 1,200 parts of the water. This is roughly equivalent to a thimbleful of sewage in every quart of city water. (See "Report of State Board of Health, Examinations of Water-Supplies," Vol. I, p. 693, just issuing from the press.)

In the course of many hundreds of examinations of the Lowell water-supply I have been unable to isolate any of the specific germs of typhoid fever. This result, however, does not prove that the typhoid bacillus was absent. From what has just been said, it may be seen how imperfect are our methods for its detection, and, as I shall show in the sequel, in spite of this result I believe, that these germs have been present in the city water in limited numbers for years, and that they were present in comparative abundance in the city water in September, October and November, 1890, owing to a special pollution. The reasons for this opinion will appear further on.

While the bacteriological results are thus inconclusive as regards the presence or absence of the germ of typhoid fever in the water-supply, it must not be supposed that the bacteriological examinations threw no light upon the question of the purity of the water. On the contrary, the numbers, and the kinds, of bacteria observed, were highly significant. When the examinations began, the dish cultures revealed a peculiar bacterial condition of the river and the low service.

In the first place, the numbers of bacteria were very high, averaging in one set of samples 2,866 per cubic centimetre (about a thimbleful) of water. This set of examinations was especially instructive and, as it is representative in certain respects, it may be quoted in full.

#### RESULTS OF A BACTERIOLOGICAL EXAMINATION OF THE MERRIMACK RIVER AND THE LOWELL CITY WATER.

1890.		Bacteria, per c.c.m.
Dec. 24.	Merrimack River, over intake	7,920
"	Upper manhole, filter gallery	3,720
"	Mixed water, gate house, Pawtucketville	4,320
"	Low service reservoir, inlet	3,780
"	Low service reservoir, outlet	3,780
Dec. 25.	Ward I. A.	1,008
"	Ward II. B.	3,180
"	Ward III. C.	960
"	Ward IV. D.	1,260
"	Ward V. E.	1,440
"	Ward VI. F.	960

NOTE.—A cubic centimetre equals very nearly a cubic one-third of an inch, or roughly, a thimbleful. It is usual for the numbers of bacteria to be somewhat smaller in the service than in the reservoir. They often appear to perish in the pipes. The Ward samples were taken from taps in private houses.

These numbers soon declined and have usually been lower, except under special circumstances of rain, thaws, etc. For example, on January 12th, six samples of tap water were taken from Wards I, III, and V, and the average per cubic centimetre was 315. On the other hand, great fluctuations were noted, showing a remarkably close connection between the river and the city water. Thus on January 22d, there was a heavy, warm rain, which carried off much of the snow that had fallen on January 16th and 18th. The rain began in the early morning. On the afternoon of the same day (January 23d), the numbers of bacteria from five taps, one each on Chestnut, Oak, Pleasant, Cady Streets, and one on Fletcher Place, averaged 15,000 germs per cubic centimetre. A few days later the same taps yielded only 500 per cubic centimetre. This is important as showing the sensitiveness of the service to changes in the river.

Even more significant than the numbers of bacteria were the kinds observed. In the earlier examinations large numbers of germs belonging to the pseudotubercle group were present. Many of these were clearly *Bacillus coli communis*; another important fact was that from this highly peculiar condition of the water there was a gradual return to a more normal condition. Too much stress can hardly be laid upon these phenomena. They were observed below Lowell, also by the biologists of the Lawrence Experiment Station, and were likewise observed in the Lawrence water-supply. I have never seen any similar condition except in cultures from faeces, and, in one case, in a polluted well located in the cellar of a house where there had been six cases of typhoid fever. In my opinion, these observations prove that in December, the river (and therefore the water-supply) was in a peculiar bacterial condition, characterized by an unusual abundance of germs ordinarily seen chiefly in sewage. What the condition may have been still earlier we can only surmise. In December the conditions were plainly favorable for bacteria of the pseudotubercle group.

Since January 1st, the numbers have been, as a rule, higher than is desirable in good drinking waters, and apparently dependent upon the condition of the river. The kinds also are such as suggest very dilute sewage, and it is difficult to see how this can fail to be the case. Whatever theories may be maintained regarding the

self-purification of rivers, there is no good evidence that the oxidations supposed to occur would destroy bacteria. When the sewage of Manchester, for example, flows into the Merrimack, it is highly probable that some of the dead organic matters are gradually removed by plants, or oxidized. But with the bacteria and all living organisms present, it is far different. These are in many cases endowed with powers of motion, and they are all aquatic in habit. For many kinds the river is not merely a grave; it is a home.

The examinations of the high service water have been especially interesting and instructive. The numbers obtained from the high service are, as a rule, much lower than those from the low service cultures. The water has the reputation, also, among many who see both, of being clearer and better. The high service, however, differs from the low only in the much longer time spent by the water in the reservoir. River water, precisely like that supplied to the low service, is once a week, or oftener if necessary, pumped up into the high service reservoir. Here it mingles with water which has already stood for several days, and there is time for settling, for "working," etc. In point of fact, I find the high service water superior to the low in chemical composition, with lower numbers of bacteria, and those of less objectionable kinds. It may of course be due to other reasons, such as the use of spring water or of good wells, but it is certainly suggestive that there have been only four or five cases of typhoid fever on the high service, and that these probably all drank low service water as well. It is more than likely that by remaining in the reservoir and by passing through a relatively long piping, some of the bacteria, and among them those of typhoid fever, die out.

I may add, at this point, that in my opinion, one cause of the recent excess of typhoid fever in Lowell has been the circumstance that the river water is so rapidly pumped into, and drawn away from, the low service reservoir. The citizens of Centralville at present often drink river water which has not even had time to settle, as my actual examinations prove.

In fine, the results of chemical examination, show conclusively what is already well known, namely, that sewage finds its way freely into the Lowell water-supply. They also fix the amount of contamination, namely, one part in every 1,200 parts. The results of bacteriological examination have failed to reveal the presence of the specific organism of typhoid fever, but they show comparatively large numbers of other bacteria, and among them, at times, forms common in sewage, and more or less characteristic of feces. A remarkably sewage-like condition was revealed by the earlier analyses. Lastly, the high service is shown to be somewhat better than the low, both chemically and bacteriologically.

#### EXAMINATION OF THE REPORTED CASES OF TYPHOID FEVER WITH SPECIAL REFERENCE TO DATE, LOCATION, WATER SUPPLY, MILK SUPPLY, ETC.<sup>2</sup>

While the foregoing investigations were in progress, a systematic canvass of the reported cases of typhoid fever was undertaken, in order to discover if the true cause of the epidemic might not come to light during a study of the actual cases affected. This laborious portion of the investigation has been done under my supervision, on the ground, with persistence and success by my assistant, Mr. George V. McLaudlin. In order

to obtain and preserve systematically all the important data, we have used a blank devised for the work of the State Board of Health. Much difficulty was found in tracing some of the cases, inasmuch as the families of the poorest classes change their dwelling place, or "move" very often. Special difficulty was found with the September cases, but it is believed that the data obtained are, for the most part, correct.

In this way, by house-to-house visitation and by special inquiry, involving a great expenditure of time and labor, all of the reported cases and all of the fatal cases have been carefully studied. In the course of this work many cases never reported have come to light, and have also been investigated. The total number of cases investigated is 550. But we have reason to believe that these are by no means all of the cases which really occurred during the period covered by our investigations.

They are distributed as follows:

1890. September . . . . .	47
October . . . . .	95
November . . . . .	171
December . . . . .	159
1891. January . . . . .	78
Total . . . . .	550

The cases reported to the Board of Health during the same period number 389.

The location (dwelling-place) of these cases when attacked is shown upon a map. It will be seen that they are concentrated in no special section, but appear to follow closely the density of the population. The high service shows about its due proportion of cases, although it is a fact that nearly, if not quite all of these, also had access to the water of the low service. It is worthy of notice that Middlesex Village (remote from the reservoir) appears to have been entirely exempt. The cases have also been plotted by months in order to see if certain regions suffered more severely at any one time, and these maps prove distinctly that the disease was not confined to any particular locality in any one month. They also show the relative intensity of the epidemic from month to month.

The relative intensity of the epidemic is more accurately shown, however, by the diagram of monthly mortality from typhoid fever. This shows the mortality from typhoid fever, month by month from July 1, 1890, to April 1, 1891. The intensity and persistence of the epidemic are manifest. The very heavy mortality of November is especially noteworthy, as is also the sluggish decline since that time. It is plain that whatever the infection may have been it dealt, suddenly, a heavy blow, from which the city has not yet fully recovered.

A more detailed and entirely trustworthy history of the cases, in point of time, has been arrived at as follows: In order to fix, if possible, the precise date of infection of each case, I determined to take the date of going to bed, as a basis upon which to work, and therefore obtain from each patient (or a friend) when possible, the exact date of illness. This proved to be satisfactory since it was usually possible to obtain this date with much precision. At the end of the investigation these dates were tabulated and plotted, and they have served as a basis for diagrams of daily and weekly morbidity.

The daily morbidity has also been shown on the diagram of the daily morbidity. Similarly, upon the diagram of weekly morbidity the weekly mortality is shown, while between these, upon the latter diagram, the dates of attack of the fatal cases are also indicated.

<sup>2</sup> The material in the first part of maps and diagrams.

From these diagrams it appears that the mortality was heaviest, and most rapid in proportion to the morbidity, early in November. A reason for this will appear beyond.

The number of persons going to bed in Lowell, with an attack of typhoid fever, on each day, from September 1, 1890, to February 1, 1891, may be readily seen from the table of daily morbidity. The course of the epidemic is more easily followed, however, upon the table of weekly morbidity. From this it appears that the epidemic began in September, rose steadily during most of October, increased very rapidly at the end of October, and especially in the first half of November; after which it fell off, but showed a marked increase every other week. An explanation of this fluctuation is offered beyond.

Inasmuch as two weeks are usually required for the incubation of the disease after the infection has been received, and in view of the foregoing facts, and of those shown upon the diagram of monthly mortality, we must obviously look for the principal infection in the last two weeks of October, although it is evident that the epidemic had begun long before this time.

On account of the canal-water theory of the causation of the epidemic, it became especially necessary to determine how many of the cases of typhoid fever might be attributable to the use of canal water. It was found, however, that while many of the cases admitted that they had drunk canal water, most of those affected with typhoid fever who had worked in the mills could not say positively whether they had, or had not, done so. I find, however, that it suffices to assume broadly that all cases among mill people might possibly be attributable to the use of canal water. For even if we do this we still have left, among those who had no possible access to canal water, a majority of the whole number of cases, and enough to constitute, by themselves alone, a serious epidemic. These facts are especially well shown upon the maps. Only 230 cases were found which could be in any case attributable to the use of canal water, while the majority, namely 320, could not possibly have been due to this cause. The canal-water theory is therefore completely disproved, for, omitting the mill cases altogether, we still have a notable epidemic to deal with. Besides, it must not be forgotten that most of the mill people when at home have access to city water exclusively, and that in one of the largest mills, the Merrimack, city water is as accessible as canal water. It is altogether too liberal to assume, as we have done for the moment, that the mill cases are all due to canal water. Some may have come from milk, or from polluted wells, or from city water. But it is now clear that if the epidemic proceeded from drinking-water at all, it must have come from the city water.

In passing, we may remark that, although the figures prove that the epidemic was not chiefly due to canal water, it does, nevertheless, appear to be true that in the epidemic the mill people suffered most severely. We might, perhaps, expect that the mortality should be heavier among the mill people than in the city at large; and this appears to be true, inasmuch as 47 of the deaths from September 1, 1890, to February 1, 1891, out of a grand total of 92 (51 per cent. of the whole number) are of mill people. We should also perhaps expect a slight excess in the number of cases among mill operatives owing to their mode of life. But certainly we should not expect that 51 per

cent. of the deaths and 42 per cent. of the cases would be among mill people, unless they were somehow peculiarly exposed to infection. It seems probable that these significant phenomena are due to the use of canal water for drinking purposes. The above figures become still more instructive if we remember that a considerable portion of the population is but slightly susceptible to typhoid fever, namely, the very young. If we reckon the susceptible population of Lowell in round numbers at 70,000, we find that the cases for the epidemic period are 7.86 per thousand. Estimating the operatives of Lowell who had access to canal water at 23,000, which is probably too high, we find the actual morbidity during the epidemic period to be one per cent., or 230.

The number required by the average for the whole susceptible population is, however, only  $23 \times 7.86 = 181$ . It is therefore safe to say that the cases among mill operatives are in excess by at least 25 per cent. Moreover, inasmuch as we know that many mill operatives probably never drank canal water, we must conclude that those who did so suffered to an extraordinary degree.

The results of the inquiry as to the kind of water actually used, or believed by themselves to have been used, by those affected by typhoid fever, are as follows:

Total number of cases investigated		520
A. Cases that possibly had access to canal water		230
a.	Those who drank canal water only	1
b.	" " canal water in part	65
c.	" " city water only	26
d.	" " city water and well water only	26
e.	" " city and other water, no canal	19
f.	" " well water only	0
g.	" " spring water only	0
h.	" " water, origin unknown	97
B. Cases that did not have access to canal water		290
a.	Those who drank city water only	252
b.	" " city water and well water	65
c.	" " spring water and well water	1
d.	" " spring water only	1
e.	" " city water boiled five minutes	1

Before we can conclude that the epidemic was caused by city water, we must remember that typhoid fever is often caused by infected milk. An investigation of the milk-supply of the actual cases, therefore, become indispensable. Among 480 cases in which the milk-supply could be traced, it was found that 135 milkmen, or milk companies, were involved. This fact alone makes the theory of widespread infection of the milk-supply extremely improbable, since these supplies came from many different farms, and in most cases had nothing in common.

#### CASES OF TYPHOID FEVER IN RELATION TO MILK SUPPLY.

	Cases.	Totals.
1 milk route had	20	20
1 " " "	11	11
2 " " "	12	24
2 " " "	11	22
5 " " "	10	50
1 " " "	9	9
7 " " "	8	56
5 " " "	7	12
5 " " "	6	34
7 " " "	5	35
11 " " "	4	11
10 " " "	3	30
25 " " "	2	50
40 " " "	1	40
Cases using milk from their own cows	11	11
Cases who were served from stores	50	50
	657	
Subtract those counted twice	17	
Total	480	

Comparison of the number of cases upon each milk route involved, with the number of people served, showed that the number of cases was nearly propor-

tional to the number of people served, the larger routes naturally having the most cases. This is usually not true of epidemics caused by infected milk. In order to make the evidence more conclusive, visits were paid to many of the sources of supply, but no evidence of possible typhoid infection was obtained at any of them. It was found, however, that many milkmen use city water with which to wash their cans.

I consider it more than likely that some cases of typhoid fever during the recent epidemic arose from the milk-supply; but on the other hand, I find no evidence whatever that leads me to attribute the principal cause to infected milk.

(To be continued.)

### THE BOHEMIAN WATERING PLACES.<sup>1</sup>

BY E. W. CUSHING, M.D., OF BOSTON, MASS.

It is not my intention this evening to enter into any minute examination of the properties and composition of the mineral waters of Bohemia, which are already well-known, but rather to give a short description of the places where these waters are found, which I visited last summer.

The Northwestern part of Bohemia, near the Saxon border, gives abundant evidences of extinct volcanic action; and here at an elevation of nearly two thousand feet above the sea-level are a number of celebrated Spas of which the three most famous are known facetiously as the Bohemian Bouquet. This nosegay is supposed to be formed of three roses, yellow, red and white respectively. The oldest and most famous spring, that of Carlsbad, is represented by the yellow rose, for here from all Europe and from distant countries are gathered patients who are yellow with jaundice; in like manner the red rose of Marienbad symbolizes the ruddy noses of the high-livers, who assemble there every summer to cool off their systems with the beneficent saline waters; the pale rose of Franzensbad matches the complexion of the anemic women, who come from far and wide to restore their health and to improve their blood by the saline chalybeate waters, hoping also to get old pelvic exudations absorbed, and congestions of the uterus relieved, by the famous mud-baths for which this locality is noted.

In all of these health-resorts there are many factors working to the advantage of the patients, besides the mineral waters themselves; and the question is worth considering whether much more benefit could not be derived from the exported waters or salts, or from the springs with which nature has provided America, if more use were made of indirect adjuvants by which the effects of the waters are so much enhanced. Chief among these aids to treatment may be mentioned the steady and systematic promotion of life out-of-door, to which end shady walks and paths are constructed and kept in order, running for miles in every direction among the beautiful hills and valleys in the neighborhood of the springs. Moreover, there are elaborate and admirable concerts by bands of forty or fifty instruments, maintained by the municipalities, and supported by a tax on all persons who visit the town for a week or more; these concerts are held in

the open air, whenever the weather permits, and tend powerfully to keep all the "cure-guests" out of doors. The whole system of taking the waters is systematically combined with as much walking as the patients can endure; and health is regained by using the waters with faith, hope and expectant attention, and also by plenty of exercise and a careful diet, good music and cheerful society, early hours and steady habits of life. Of course, the patients are more impressed by the facts that they are drinking the waters, than by the indirect advantages which they are receiving at the same time, but the skilful and highly-educated physicians who practise in these localities are always careful to insist on suitable diet, and a proper amount of exercise.

Carlsbad, which is now probably the most celebrated watering-place in the world, where over 20,000 guests congregate annually, has been known for centuries for its hot springs, of which the most celebrated is the "Sprudel" or spouter, which comes foaming up in a jet several feet high with occasional short intermissions. The surface waters of the surrounding country percolate down through the soil and decomposed rocks of this region, to a depth of 8,000 feet or more, becoming highly charged with carbonic acid, sulphate of soda, bicarbonate of soda, chloride of sodium and various salts of less importance. The heat of the earth increases the pressure of gas held in solution to such an extent as to force the water up again through a crevice, thus yielding a steady flow of the mineral water through various springs, which are cooler and more highly charged with gas according to their greater distance from the hot and foaming Sprudel.

Among the diseases in which particular benefit is claimed from the use of these waters are hepatic affections, such as passive congestion of the liver and the early stages of cirrhosis and of fatty liver. Even greater advantage is derived in cases of catarrhal jaundice and of gall-stones, as well as in catarrh of the stomach, and in chronic gastro-intestinal hyperemia, also in habitual constipation due to sedentary habits, or torpor of the liver and catarrh. The uric acid diathesis and gout in all forms are greatly benefited by these waters. Carlsbad also has a high reputation for ameliorating the symptoms and retarding the progress of diabetes mellitus, although there are different opinions as to how much of the advantage is due to the use of the water and how much to the careful dietetic treatment employed there. Great benefit is often derived at Carlsbad by patients suffering from obesity and from various forms of chronic metritis, although the first of these affections is considered to be more particularly adapted to treatment by Marienbad water, and the latter ailment belongs rather to Franzensbad. Of course, however, all three resorts endeavor to benefit as many classes of disease as possible, and, therefore, the peat from Franzensbad is brought to Carlsbad to give mud-baths, and the latter are also given at Marienbad from peat found in that vicinity.

Marienbad is distant about three hours by railway from Carlsbad. These two places and Franzensbad are on a sort of triangle. The waters are somewhat similar to those of Carlsbad, except that they are cold instead of hot, are twice as strong in sulphate of soda and have a trace of iron. I shall not go into a particular analysis of these waters. The main ingredients

<sup>1</sup> Read before the Boston Bar, Clinical Medicine, Pathology and Hygiene, at the request of the Boston Medical Society, February 11, 1891.

are the sulphate of soda, the carbonate of soda and some chloride of sodium. The Marienbad waters act more on the intestines, and are more adapted for gastro-intestinal catarrh, for catarrh of the stomach, and for obesity, and in fact, wherever the purgative action is more desired. The Carlsbad water is not purgative as used at Carlsbad. Taken hot and slowly, quite a considerable amount can be taken without exciting any purgative action. The same system prevails as at Carlsbad of having beautiful walks through the pine woods which are all around the town, and of keeping out of doors. In stormy weather places are provided in both these towns for walking under cover. At Carlsbad there are two great colonnades of stone, the chief of which is the Sprudel Colonnade which extends perhaps two hundred feet, and another place where early in the morning the band begins to play and the people walk around taking their water, each going in turn with a little cup which hangs over the shoulder by a strap, and which is filled by the girls who stand ready to do this.

The most important question is as to what can be done with these waters, for those who cannot go to Carlsbad. Although the number of guests has risen from a few hundred to twenty thousand a year, yet everybody cannot go there, or stay there as long as he would like, and gradually there has grown up an immense exportation of the Carlsbad waters, and of the salts which are manufactured on a large scale and must be largely used, or they would not be exported. Without going into the question as to whether there is any particular advantage in natural mineral waters over those which are artificial, a subject on which there may be two opinions, it seems to me that the one thing which is apt to be lacking in using artificial waters at home is the example of the other patients, the faith and the expectant attention which is gained by seeing so many there, and by seeing everybody believing. This tends to make all persevere with the treatment, get up early and take their walks, whereas, at home they could not seem to get away from their business, while they not only are not so much encouraged to follow the advice of their physician, but the medical attendants at home do not give the exact advice and the stringent orders which the physicians there do; and it seems to me that with the use of any of these waters a great deal lies with the physician in laying down strict and exact rules. If you have a patient with a swollen joint which requires rubbing, you order a liniment, and you could not get the rubbing done unless you ordered a liniment. The patient pays for the liniment, and the rubbing is thrown in, and he gets better. The same way with the use of mineral waters. The waters may be good, but unless combined with diet and fresh air and exercise and freedom from care, the results are apt to be disappointing.

It is a long way from Carlsbad to this country, and therefore the salts which are manufactured by L. Schottländer, the lessee of the springs, are used more than the waters. As the waters are boiled in vats, the lime, manganese and iron are precipitated by the expulsion of the carbonic acid. The elimination of the lime is considered no loss. Formerly they used the crystals, and all one would get in the crystals would be the sulphate, carbonate and chloride of sodium, losing most or all of the other substances which are present in small proportions. They have recently intro-

duced the following method: the water is boiled down until it is just on the point of crystallizing. It is then run on to a great hot roller, which turns slowly, just fast enough so that the dense solution runs on over one side, and by the time the water gets to the other side of that roller it is crystallized and is scraped off. These crystals are dried in trays, but that does not do the whole of it. By this process the bicarbonate of soda has been reduced to the common carbonate, and it is desirable to get back that carbonic acid. To accomplish this, carbonic-acid gas from the Sprudel is lead over the trays, and in course of time the salts absorb carbonic acid, remaking bicarbonate of soda, and then (except for the presence of lime which is not wanted) the salts very closely represent the Carlsbad water, so that by making a solution of these salts you could get very nearly a representation of the water; but the patient does not get the advantage of the locality, fresh air and faith—all these the physician must arrange for him as best he can.

There is some advantage in using the water at home. Sir Henry Thompson pointed out that persons who go to Carlsbad often rush away too soon. Time is limited, and they take more exercise than they can well endure, more water than they need.

"When a stout, active man, whom it is most desirable to separate from his home engagements and business cares, requires a Carlsbad course, he may often visit the locality with advantage. At the same time, as I have already intimated, I firmly believe that it can in the majority of instances be more successfully pursued at home, provided certain concomitant advantages can be secured, than by sending the patient abroad. Thus, it is desirable to secure during a course of waters at home, at least regularity of meals, scrupulous attention to diet, and to select a time when, particularly in the case of business men, less of anxiety and of need for over-exertion than usual may be expected. Granted these conditions, there is one advantage in the home course which outweighs much of the special value of a course on the spot. The patient who stays at Carlsbad three weeks, very rarely four, is made to consume far too large a quantity of water in a given space of time. The quantity in itself is probably not too much for his needs, but it is more efficacious, and is less exhausting in its effect on the patient, to devote two or three months to the task than to swallow the whole within the brief term named. It is the apprehension of this fact which has made me so warm an advocate for the systematic home use of these agents."<sup>2</sup>

The third place of which I will speak is Franzensbad, which is in this neighborhood. It is really a suburb of the town of Eger, where Wallenstein was murdered. It lies not so conveniently as Carlsbad and Marienbad, with hills and woods close to it, but more in a flat plain with hills two or three miles away. It is a very curious geological formation; there is a small crater of a volcano not far from the town, long extinct, and there are large deposits, at what is known as the "Soos," of a substance called *Moor*, which is a black mineral peat very strongly impregnated with iron pyrites. This peat is dug up and exposed to the air and moisture. The iron pyrites by a well-known chemical process is decomposed into sulphate of iron; but besides this salt with which the peat is impregnated there are the remains of vegetable products, with vari-

<sup>2</sup> Sir Henry Thompson: *Calculeous Disease*, pp. 32, 33.

ous resins and a considerable amount of formic acid. The peat looks a good deal like what we should call salt-marsh earth, as seen in meadows where the tide-water runs up. It is black, and will not support vegetation; and the great peculiarity of it is the large amount of iron which it contains. This peat is exported to Carlsbad. A similar substance, but not containing so much iron, is found in Marienbad.

What property of the mud-bath is the chief factor in producing its effects is a question in dispute. Some think it is the iron, and the vegetable components which are in this black liquid. Others pay more attention to the warmth and pressure. I took a mud bath. It is a peculiar sensation. One settles down slowly into this strong poultice; one cannot sink right down into it as into water, but has to work his way down, and it feels as if a warm coverlet were tucked around one. In Franzensbad the bath is heated by steam. In Carlsbad the peat is mixed with hot Sprudel water. It exerts a considerable action on the skin. It increases the bodily temperature, excites the heart, and some care has to be taken with persons having a tendency towards congestion of the head, etc. It is a pretty powerful therapeutic measure. It is claimed that it is highly efficacious in promoting the absorption of abdominal deposits.

There is the usual system at Franzensbad in regard to music; and most of the women there not being very strong, not so much attention is paid to lung walks, but they sit around under the trees in the park, and knit and crochet, and take their water, and hear the band play, and do some shopping. I think a large part of the advantage is this: that women overworked, caring for large families, are able to get away from their homes, their husbands, and their cares, have a period of perfect rest, go to bed at nine o'clock, have these saline and chalybeate waters and the mud-baths, and I have no doubt they are vastly improved. That they are not entirely cured is seen from the fact that they keep coming back.

The waters of Franzensbad are of the same general nature as the others, in that they contain sulphate of soda and carbonate of soda, with the addition, however, of considerable carbonate of iron.

Marienbad and Franzensbad waters are bottled and exported, and are also boiled down and crystallized, but the iron is cast out in so doing. Iron in mineral waters is a very difficult thing to preserve or transport; and the Marienbad water does not contain it except in very slight amount, which becomes turbid on standing. In the Franzensbad salts there is no pretence that iron is retained, therefore they resemble the salines from the other springs above mentioned.

To go a little more into detail in regard to the treatment at Franzensbad, it is somewhat peculiar. It is the stronghold and abiding-place of local medical treatment of diseases of women, as distinct from the surgical treatment, so much so that none of the physicians there will do any surgical operation whatever, unless to cure for hemorrhage or something like that. Men from different parts of Europe send patients there, with the understanding that they are to be treated but not operated on; and if they cannot be improved, they are sent back and operated on elsewhere. It is there that the system of massage has been largely developed, and is practised by Dr. Fellner, who was kind enough to show me some of the cases, and by various other gentlemen. They are treating by

gentle massage what we should once have considered chronic pelvic cellulitis, but call now cases of mild salpingitis with adhesions, the principle of the massage being to lift the uterus with one finger in the vagina and to try to get behind the uterus the fingers of the other hand on the abdomen and to soften up adhesions around it by gentle pressure. I should imagine in some cases where there are slight adhesions, with no particular inflammatory condition present, that massage with the mud-baths and the water, might be a very good thing. Some of the cases I saw treated with massage, I am bold to say, will have to come to laparotomy. But the principle they go on is to give rest and packing and massage and electricity, and do no operating, even prolapse of the uterus is there treated by massage.

A solid and a liquid extract made from the peat are prepared and exported by Mattoni, and are used in baths at Vienna, Prague and elsewhere; they can be obtained in New York, and are coming into extensive use in this country.

At all these Spas, and especially at Carlsbad, after the main season, which ends in the middle of August, there comes a great influx of people who cannot pay the full price for lodgings, etc. After the festival of the Emperor, August 18th, the company changes; the fashionable people disband, and the unfashionable people come.

The season proper in all of these places is from about from the middle of June to the middle of August. Two months only comprise the height of the season. The physicians who practice there most of them do not practice elsewhere. They made a long season, come about the middle of April and stay until about the middle of October.

Carlsbad is open for guests all winter. A person can go there then and live cheaply; but at that season it lacks all those beneficent auxiliaries, — the crowd, the walks, open air and the music, so that except for special reasons patients only go in the summer, preferring to make a little winter Carlsbad at home by using the exported waters or salts.

#### DISCUSSION.

DR. LIEBMANN: I was highly interested in the paper. It covers the whole ground. I would only repeat to-night what I have already had occasion to say some time ago about not enough care being taken by the general practitioner in the selection of certain cases, especially stomach cases, to be sent to Carlsbad. As the doctor remarked, Carlsbad does a great deal for organic diseases (especially of the stomach and liver), for chronic catarrh and hypersecretion of the gastric juice, and hyperacidity of the stomach; but it seems to me that at least twenty per cent. of all stomach cases are of the neurotic kind, at least I find that to be the case in my experience, and I have found that, to send these and especially neurasthenics, to Carlsbad, is followed by very bad consequences. They come back in a very depressed and wretched condition. I have now a patient whom I intend sending to Carlsbad who is suffering with gall-stones, and I suppose and hope his case will be benefited; but I confess I have always some hesitation in making up my mind to send anybody to Carlsbad. In case of gall-stones we do not know how the waters act. We know that the stones pass much more readily than under any other treatment. With regard to the *modus operandi* of the waters in

gastric trouble, such as catarrh, we can better see into it, if we remember that in our every-day routine of irrigation of the stomach if we add some bicarbonate of soda to the irrigating fluid we see how the mucus that has been very abundant before is decreased by the addition of the alkali to the water. And also in hypersecretion or hyperacidity of the gastric juice it can be readily understood that it dilates the juice and brings about an improvement in the feeling of the patient.

The reason why patients of the neurasthenic kind are injured by the treatment at Carlsbad is because the treatment is depleting, the cure a trying one and they need a sustaining and roborant regime.

DR. C. P. PENGRA: The remarks of the evening call to mind a case I have seen in the city. The case is more or less of the nervous variety. So far as I can see, it is simply a case of the uric acid diathesis. The patient will go to Carlsbad, and return perfectly cleaned up, as you might say, of his uric acid. He will remain so for perhaps three months, then he will be troubled with a sort of phantom tumors. I have watched him within a few months. As his attention will be called to it, his abdomen will begin to swell and reach dimensions which in the female might be attributed to the pregnant condition. Following that perhaps he will pass a teaspoonful of urine, and the tumor will disappear. He has learned to recognize that as the beginning of his next uric acid trouble; and this has occurred with considerable regularity now for three or four years. He goes to Carlsbad every summer; is relieved of his condition and of the uric acid; comes back here; and in the course of a short time is troubled with this tumor or enlargement. Gradually his uric acid condition appears again; and to my knowledge he has not succeeded in finding anything that would relieve him but the Carlsbad treatment, but what treatment I do not know.

## PROSTATOTOMY IN A PATIENT OF FORTY-TWO.

BY ARNER POST, M.D.,  
Visiting Surgeon, Boston City Hospital.

THE object of this short paper is simply to give the history of a case of prostatic enlargement which presented exceptional features in the age of the patient and the character of the growth, and some serious questions as to the proper method of treatment.

Peter Hamell, aged forty-two, entered the Boston City Hospital May 5, 1887, with the diagnosis of stricture. He was a French Canadian, and while anxious to tell us everything of interest, his history was not fully known to us until just before he finally left us. He never told us all we should have been glad to know about the earlier symptoms of his trouble.

The first fact in his history pointing to trouble with his urinary organs dated back twenty-one years to the time when he was twenty-one years old. At that time he was partially buried by the caving-in of an embankment. He lay insensible for two hours, and when, on gaining consciousness, he desired to pass water, he passed a certain amount of blood. Ever since that date he had been obliged to strain in order to pass his water. When twenty-three years old a doctor tried to pass an instrument, but did not succeed in entering the bladder.

When thirty years old he had a clap, and in the course of that disease another doctor attempted to pass an instrument into the bladder, but he also failed. Later he had had a second clap, and also venereal ulcers, which were followed by symptoms of constitutional syphilis.

For more than ten years previous to our acquaintance with him, the man had been obliged to lift up his perineum with one hand, even passing his finger just within the anus and pressing or rubbing the urethra to start the urine. The first discharge consisted of pus or glairy mucus. His bladder was imperfectly emptied, and at the time he entered the hospital he was obliged to go through this milking process from five to eleven times every night. His urine was alkaline, and contained pus, blood and bladder epithelium.

He came into my hands from another hospital where it was supposed electrolysis had been applied. He also believed that an instrument had been passed into the bladder under ether, but no instrument had been passed subsequently, though repeated attempts had been made.

The meatus admitted a No. 22 (French) acorn bougie, which passed without obstruction to the bulb. A solid steel sound of the same size was arrested in the prostatic region. The finger in the rectum then recognized a notable enlargement of the prostate, which was unusually firm and not in the least tender. The enlargement was slightly more prominent on one side, but perfectly smooth, and so large that the finger could not reach beyond its upper border. Attempts were then made to pass other instruments but nothing could be made to enter the bladder.

For a month the patient was treated with ergot and hot rectal injections. It was thought at one time that the prostatic enlargement was diminishing, but as little change took place in the symptoms and no instrument was ever passed, this was undoubtedly an illusion, and on June 9th the patient was etherized, the urethra opened in the perineum, and attempts made to pass an instrument into the bladder through the perineal opening, but without success. The finger passed along the urethra brought up against a solid wall in the prostate on which it could make no impression. An exceptional condition was evident, and the operation was abandoned for the time being.

Soon after the patient broke out with a palmar and plantar syphilide though no signs of syphilis had been noticed before. The injury, the hæmaturia and the long history of difficult micturition was unknown at that time and the question arose as to whether the disease in the prostate could possibly be some unknown syphilitic manifestation. Without any definite idea that the prostatic enlargement could be due to syphilis it was thought proper to submit him to anti-syphilitic medication before further operative procedure, and he was accordingly submitted, at first to mercurial and afterwards to mixed treatment, but as might have been foreseen, no change took place in the prostate, though his frequent micturition was so far reduced that he was able to hold his water for three hours.

On November 9th he was again etherized. The perineal opening was again made as before. Nothing could be passed into the bladder; the same wall was presented to the finger. A director was then passed against the prostatic obstruction, its position verified by a finger in the rectum, and a knife passed along the director and through the prostate into the bladder, the

director following the knife. On withdrawing the knife, urine flowed along the director, but the resistance was so great that no catheter could be passed along the director, and the finger was as powerless to enter as before the incision. A Bigelow's sinus dilator was then passed and opened, the prostate giving way with an audible crack. In this way the opening was enlarged so as to admit the finger. The walls on each side were of almost stony hardness, or, more exactly, like a fibrous tumor. The finger with difficulty felt the extreme edge of the prostatic tumor. The largest-sized drainage-tube was introduced, with a second tube contained in it and this tube left open so that all urine was carried off immediately. There was practically no constitutional disturbance. The tube was worn for a month, at the end of which time it was permanently removed, and the perineal opening rapidly closed. After the removal of the tube, instruments were passed from the meatus every two or three days, but the only instrument that entered the bladder was a straight one. Urine could be drawn only by passing a straight silver catheter, open at the end, and through that a flexible French catheter. The patient was able, however, to project his urine in a stream, and was disturbed but once in the night. His urine became acid, and contained but few pus cells. It was a great treat to him to display the stream, though before the operation I could never get him to pass water in my presence.

There are several interesting points in connection with this case.

In regard to the nature of the prostatic growth, I am not inclined to look upon it as a case of hypertrophy of the same nature as the senile cases, occurring at an unusually early age. The patient when first seen was forty-two. His history showed that trouble with micturition and presumably the prostatic trouble had existed since he was twenty-one. In hardness it resembled most closely a fibrous tumor, and as such I believe it ought to be classed. It is a matter of regret that a portion was not excised for the purpose of examination.

The choice of operation was a matter of great importance. The suprapubic operation, of course, suggested itself, but the objections seemed to outweigh the advantages. It would have been impossible to properly fill the bladder as a preliminary to the operation. It was also impossible to wash out the bladder, and the operation would have involved the contact of decomposing urine with the cut surfaces. In addition, the operation involved a retrograde catheterism after the bladder was opened, which did not promise to succeed; and a blind cut to enlarge the vesical orifice seemed more likely to be a success if made from the urethra into the larger hollow of the bladder than if made in the other direction.

As a preliminary to such an operation in the perineum, it is desirable, if not necessary, that the bladder be distended by a certain amount of fluid. One advantage gained from the long delay was a greater interval between micturition, allowing the accumulation of a larger amount of urine in the bladder.

This patient was seen two years after the operation, when he had had no return of symptoms.

## SOME PRACTICAL HINTS IN THE USE OF PLASTER-OF-PARIS BANDAGES.

BY JOEL E. GOLDTHWAIT, M.D., BOSTON.

PROBABLY every one who has used plaster-of-Paris in bandages, has at one time or another experienced difficulty in its use, because of the length of time required for it to become hard. It is usual in such cases to blame the plaster; the prevalent belief being that it has absorbed moisture and is partially slaked. Of course this is possible; but as a matter of fact, it requires a very humid atmosphere to affect its quality, and in proof of this, the plaster is put up in cheap pervious casks, and is shipped from the Provinces, where most of it is ground, on ordinary coasting vessels, and is finally stored in warehouses that are very far from being impervious to the outside air, whether it be dry or moist. It is perfectly reasonable to expect plaster-of-Paris to keep even after it has been opened, almost indefinitely in any place that is not noticeably damp.

The principal reason why plaster sets so slowly, when used in bandages, lies in the bandage itself. Dr. V. P. Gibney, of New York, found that much of the creoline, which is ordinarily used in making the bandages, is sized with glue, and that plaster to which glue has been added hardens slowly. Occasionally a piece of creoline is found that is sized with starch rather than glue, and this interferes in no way with the rapid setting of the plaster. This explains the fact that at times one lot of bandages will work beautifully, while the very next lot will try every one's patience by taking so long a time to become hard. As it is impossible to tell, before using, what the creoline has been stiffened with, whether glue or starch, it should all be treated alike and the sizing be removed. This may be done very easily by simply washing the creoline in warm water and allowing it to dry thoroughly; and plaster bandages made with this washed material can be depended upon to harden very rapidly. (It will be found more convenient to wash the creoline after it has been torn into bandages, as it does not tear so readily after washing.) After the bandage has been applied the plaster should be thoroughly rubbed into the mesh of the cloth, as the strength of the bandage as well as the rapidity of hardening will depend considerably upon this.

No salt should be used in the water, in which the bandages are allowed to soak. This makes the plaster brittle, and to possess the same strength it would have to be considerably thicker and heavier.

The removal of the plaster-of-Paris bandage has always been a source of annoyance. This can be done very easily in the following manner: An ordinary pruning knife may be used, or what is more ele-

gant, an instrument that is made by Tarter of New York, the convex surface of which is a saw, while the concave upper edge is a sharp knife. As a matter of fact the saw is almost never used. The bandage is scored with the point of the knife, wherever it is wished to open it. A few drops of water are run into this groove from a medicine dropper. The knife is then drawn firmly along this line, and the plaster thus moistened is found to be soft and easily cut. A few more drops of water and a few more strokes of the knife and the bandage is divided. There is no

WHITE HATS. — It is reported, that in Berlin physicians' coachmen are heretofore to wear white hats, in order that they may be readily seen on the streets, and summoned if wanted.

danger of cutting the patient, because if the cut is made from above downwards, the tendency of the knife is to draw out or away from the skin.

In conclusion I would summarize as follows: By using crenoline from which the sizing has been removed, by carefully working the plaster-of-Paris into the mesh of the cloth, and without the use of salt, a bandage may be applied that shall be no heavier than those made of dextrine or silicate of potash, but which shall possess more strength than either of these, and which will harden almost as rapidly as it can be applied. In the removal of the bandage, the plaster should be moistened, and it can be cut most conveniently with a knife having a concave edge.

#### ON AN APPLICATION OF AGAR-PLATE CULTURES TO WATER ANALYSIS, WITH SPECIAL REFERENCE TO THE DETECTION OF THE BACILLUS OF TYPHOID FEVER.

BY ALLEN HAZEN AND F. W. WHITE,  
Of the Lawrence Experiment Station of the State Board of Health of  
Massachusetts.

In determining the number of bacteria in waters by Koch's gelatine-plate process, the rapidity of growth of the colonies is largely dependent upon the temperature. Probably the best average temperature for the growth of bacteria in general, is that of an ordinary room, namely, 15° to 20° C., and, as a rule, the common forms of bacteria found in unpolluted waters, grow best at this temperature, while higher temperatures check or retard their growth.

There is, however, another class of bacteria, the parasitic germs, which, normally habituated to the bodies of warm-blooded animals, grow best at blood-heat, although usually they do grow more or less at lower temperatures.

Bearing these facts in mind, we can readily understand what takes place in a gelatine plate containing bacteria of both these classes, as, for example, a plate made from a sewage-polluted water containing typhoid fever germs, and which is cultivated at the ordinary temperature. Most of the common species are well suited to this temperature, and grow rapidly into large colonies, while the pathogenic germs are retarded in their growth, the temperature being nearly 20° below their normal. The chance of finding these pathogenic germs is thus comparatively small, since the common germs, having the advantage over the former in more congenial temperature conditions, grow vigorously, and cover the plate, especially if they liquefy the gelatine, before the pathogenic germs have time to form colonies large enough to be recognized.

It seemed to us altogether probable that, if the plates could be kept at blood-heat, the above conditions would be reversed, the common germ retarded and the pathogenic germ favored, so that the chances of finding the latter when present might be greatly increased. Unfortunately, gelatine, even when made much stronger than usual, is melted far below this temperature, and so some other substance must be used for this purpose. Agar, when made up with bouillon according to Koch's formula, in two per cent. solution, melts at about 90° C., and solidifies again at about 50° C., and can be kept indefinitely at blood-heat without softening. It is, of course, inadmissible to mix the water to be examined with melted agar at 90°, or even 50° C.,

because even this temperature might kill a portion of the bacteria, but if the agar is thoroughly melted in boiling water, and then suddenly plunged into water at 40° C., it can be cooled to this temperature without instantly solidifying. While the agar is in this condition, fluid, and yet cool enough for safety, the water to be examined is quickly mixed with it, and the whole poured out upon a glass plate, when it almost instantly solidifies. There is ample time to perform this operation, but there must be no delay, for the agar will not long remain liquid. This method of making agar plates is already well known.

Using Petri double dishes, instead of plain glass plates, moisture often rises from the agar, and condensing upon the cooler cover, falls back on the agar, and softens it in places, so that the colonies extend unduly on the surface. We find that this can readily be prevented by turning the dishes upside down. The plates are almost always sufficiently developed in twenty-four hours, and there is no liquefaction by the colonies.

We have applied the method very successfully to the isolation of typhoid-fever germs from river water inoculated with a minute quantity of the bacilli, the agar plate sometimes presenting, after only twelve hours incubation in the thermostat, almost a pure culture of these germs. Using faeces from a typhoid patient, the typhoid germs were often detected when the gelatine plates failed to show them, though in this case the plates also contain *Bacillus coli commune* and others from the intestines. It is probably in this direction that the method has its greatest practical outlook, namely, as an improved and rapid method for detecting pathogenic germs in drinking water, in faeces, etc.

Gelatine plates, grown in the ordinary way, give approximately the total number of bacteria of all kinds present, making especially prominent by rapid growth and large colonies, the common forms growing at low temperatures. Agar plates on the other hand, incubated in the thermostat, present a selected number, namely, those which can live at blood-heat, including, we may believe, most of the parasitic and pathogenic germs, which, under the circumstances, are the ones of greatest interest; and eliminating those species which cannot grow at the temperature of the body, and are, therefore, in most cases, as such, presumably harmless.

#### RECENT PROGRESS IN SURGERY.<sup>1</sup>

BY H. L. BURRELL, M.D. AND H. W. CUSHING, M.D.

##### LIGATION OF THE VENA SAPHENA MAGNA FOR VARICOSE ULCERS OF THE LOWER LEG.

TRENDELENBURG<sup>26</sup> advocates the ligation of this vein for the relief of varices and ulcers of the lower leg. Briefly the rationale of this treatment depends on the theory that the superficial venous system forms with the deep veins of the leg through the communicating branches, a vascular circle. When the varicose condition of the former exists, the circulation towards the vena cava through the large saphenous vein, on account of the weight of the column of blood and other causes, is greatly impeded. The vein is relieved by the escape of blood through the communicating veins into the

<sup>1</sup> Continued from page 387.

<sup>26</sup> *Beitrag z. Klin. Chir.*, 1890, Bd. vii, 195.

deep vessels of the leg. But the relief thus effected is counteracted by the superficial vein refilling from its proximal end as fast as the pressure is relieved by the escape of its contents distally as above described, thus forming a system of more or less independent venous circulation. By high ligation of the superficial saphenous trunk this is stopped, producing the same result with the patient erect, that is effected by placing the patient recumbent with the legs elevated. The main trunk of the vein should be ligated, at a point above the varicose condition, generally in the middle or lower third of the thigh. The vein is exposed by a straight incision three centimetres long, isolated with the end of a scalpel and surrounded by a double catgut ligature. The leg is elevated to allow the vein to empty, the ligatures are tied, and the vein divided between them. The skin incision is then sutured. The results of this treatment are claimed to be quite satisfactory.

#### ON THE ORGANIZATION AND ABSORPTION OF STERILIZED DEAD BONE DOWELS.

Penrose and Hopkins<sup>29</sup> after experimentation, conclude that such dowels under favorable circumstances can become organized while in contact with living bone tissue. When exposed to great activity of the periosteum it results in their absorption. When implanted in the medullary canal of the bone they are partly organized, partly absorbed. The results appear at the end of five to eight weeks without symptoms of inflammation. When used to fix bones in osteoplastic amputations or resections, the power of fixation can be depended upon four, or at the most, six weeks, after which a gradual absorption occurs. This time is usually enough for the bone to unite.

#### ACUTE ARTHRITIS OF INFANTS.

In an extremely valuable article W. R. Townsend<sup>30</sup> has collated what cases have appeared in literature on this disease, and has formulated the following conclusions:

(1) Acute arthritis of infants occurs most frequently during the first year of life.

(2) It is pyæmic in character, an osteomyelitis of infant life, and is caused by one of the forms of staphylococci, most frequently the staphylococcus albus or aureus; may follow traumatism of the exanthemata.

(3) The most frequent site of infection is the epiphysis near the joint, which in early life is frequently intracapsular.

(4) The disease progresses rapidly and nearly fifty per cent. of the cases have terminated fatally, the most frequent cause of death being exhaustion.

(5) A more or less complete destruction of the "joint end" of the bone, pathological dislocations, flail-like joints and loss of length of limb, rarely ankylosis, are the most common results of the disease.

(6) Disease is most frequently met with in hip, knee and shoulder.

(7) As soon as the disease is recognized the pus should be evacuated promptly, the joint properly drained, and parts dressed antiseptically.

(8) The treatment of resulting deformities should be conducted on general orthopaedic principles.

#### TREATMENT OF JOINTS.

Dr. Brounslaw S. Kozlowski<sup>31</sup> has contributed a valuable monograph, based on 272 cases which have been carefully followed out to their ultimate results. He draws these general conclusions from his own clinical researches and the study of international literature:

(1) In children, conservative methods should be preferred to operative ones, even in the presence of suppurative and disorganization of the joint. Such treatment gives by far the superior results in regard both to the patient's life and usefulness of the limb.

(2) An operative treatment in children may be indicated only in such cases of articular tuberculosis of the upper limb where very considerable suppurative and disorganization of the joint are present. Whatever the operation decided upon, all possible attempts at preserving epiphyseal cartilages should be made in order to prevent a consecutive shortening of the limb.

(3) In adults, conservative treatment should be preferred in all cases where no suppurative and disorganization of the joint have yet set in.

(4) An operative treatment in adults is indicated only in the presence of suppurative and disorganization of the joint, though even here a conservative method should be preferred as soon as the lesion is limited to some circumscribed foci.

(5) As far as adults are concerned, in the case of upper limbs, resection is followed by more satisfactory functional results than a conservative treatment, but in the case of the lower limbs conservative methods prove more successful than operative ones.

(6) In cases of multiple tubercular lesions of bones and joints, a local treatment alone utterly fails to cure the patient. It can prove beneficial only when combined with an appropriate general treatment.

(7) A conservative treatment of osseous and articular tuberculosis deserves most careful attention of the profession. All conservative cases should be published by surgeons as systematically, and described as carefully, as those treated after operative methods.

#### TUBERCULOUS ARTHRITIS OF THE KNEE AND ITS SURGICAL TREATMENT.

Pritchard<sup>32</sup> has written an interesting and valuable review of the work and opinions of several Scandinavian surgeons in this branch of surgery. Both the original papers and the review are too extended to be reported in full, but the following facts deserve mention. Dr. Müller, of Copenhagen, after an analysis of forty-two cases, concludes that arthrectomy should hold preference to all other procedures and conservative treatment. It has no danger to life. He had only two deaths in his forty-two cases, which he accounts for in other ways. He claims that the length of treatment was on an average 7.3 weeks, and when uncomplicated, much shorter, patients leaving their bed in six, four and even three weeks. He thinks that an operation may prevent general tuberculous inoculation. He claims 66.7 per cent. of cures from his set of arthrectomies, against 71 to 77 per cent. from the newer resections in other countries. Pritchard thinks this claim not warranted by the data published by the writer, and his reasons for thinking so seem to be good ones. Hence this statement (Müller's) of his end results must be regarded at present as not sus-

<sup>29</sup> *Journal of American Medical Association*, 1890, vol. xiv, No. 11.

<sup>30</sup> *American Journal of Medical Science*, January, 1890.

<sup>31</sup> Inaugural Dissertation, St. Petersburg: *Annals of Surgery*, December, 1890.

<sup>32</sup> *Annals of Surgery*, 1890, vol. xii, 293.

tained by fact. As regards functional results he reports 18 cases in children aged two to ten years. In the greater number of these shortening was not essential. In five cases he reports that a distinct lengthening of the limb occurred; in two cases as much as two centimetres. In regard to adhesions, in 25 cases he found flexion 17 times, as a rule, not marked; complete extension in eight cases. In these eight cases six, or perhaps seven, had active mobility. Mobility existed only once in the 17 cases of flexion. He therefore considered the muscles the agent in causing the contractures and states that "one must be insane to want to induce ankylosis after arthrectomy."

He advocates strongly in cases of incomplete ankylosis that baths, massage, electricity and passive motion to increase active mobility.

Dr. Strom, of Christiania, bases his investigations on 200 cases treated from 1873 to 1887. He classifies them pathologically into the fungous arthritis (tumor albus), caries sicca (Volkmann), tuberculous hydrops, and cold abscess; and he tries to demonstrate how clinically prognosis and treatment are decided by the variety of disease present. In regard to operating he thinks this removes the principal focus of disease and will thus diminish the mortality of general tuberculosis. The danger of general inoculation resulting from operation, he considers as exaggerated. Operation has given the best results in children, aged five to fifteen, especially in arthritis sicca. The most unfavorable results were in cases of tuberculous hydrops, functional results not especially good. In 37 cases, two had good motion, two some motion and moderate contracture, the rest ankylosis with more or less flexion. He considered arthrectomy and resection as the true operations for knee-joint tuberculosis, since they give free access to the joint, and permit total removal of the diseased tissue. Of the two, he would form resection in adults. With children he is still in doubt. In regard to amputation, he regards age as an important consideration. He considers 50 to 55 years of age a positive indication for primary amputation. In general, he would amputate the thigh when he could not hope to obtain a serviceable extremity by more conservative manner, or where there are signs of the secondary consequences of the disease, or a prospect of their appearing. Amputation is rarely required under twenty years of age, but more often between twenty and fifty, the liability for disastrous results to follow persistent suppuration, increasing with the age of the patient. If resection cannot remove the entire source of pus, or there is extensive tuberculous infiltration of the soft parts, amputation is necessary. In this he differs from many surgeons. Amputation should be done where internal organs are extensively involved. He obtained the best results from his arthrectomies where he removed simultaneously the diseased soft parts. He noticed, also, elongation of the limb as reported by Müller, in two cases, a result of considerable annoyance to the patient. He thinks it due to the congestion and increased development of the blood-vessels in the epiphysis from removal of the capsule so near this point. In tuberculous gonitis in children he prefers arthrectomy and opens the joint with a transverse incision above or through the patella.

(To be continued.)

## Reports of Societies.

### THE NEW YORK NEUROLOGICAL SOCIETY.

MEETING of March 3, 1891, the Vice-President, DR. B. SACHS in the chair.

#### AN HEREDITARY TYPE OF MOTOR TABES.

DR. PHILIP COOMBS KNAPP, of Boston, read a paper with this title. The case forming the subject of his remarks was one of muscular atrophy, occurring in a man thirty-four years of age. The trouble had begun with fibrillary twitches in the muscles of the right thigh, followed by weakness and atrophy. There were no sensory disturbances. Faradic excitability was lost and galvanic excitability diminished, and the contractions were slow. The disease had progressed steadily, both legs becoming helpless and atrophied. The fibrillary twitches finally appeared in the muscles of the shoulder and upper arm. There was a history of a kick in the right thigh, not of a very serious character, a few months before the onset of the symptoms. There was also a history of a peculiar affection in the patient's mother's family, of which the mother and at least four others in preceding generations had died. The affection was marked by paralysis of all the limbs, and in no case had there been atrophy. All the attacks had come on in middle life. The case reported was regarded as of spinal origin, and it was thought that the family disease was also spinal. In connection with this case, an instance of typical Aran-Duchenne atrophy, beginning in the thumb muscles was reported, the patient's father having died of a similar trouble. A case of progressive atrophy with bulbar symptoms was also cited, dating from a fall on the elbow.

DR. W. R. BIRDSALL said that the history detailed in the paper of Dr. Knapp had brought to his mind numerous cases of traumatic tabes in which accident had developed some local sensory or motor neuroses a good many years before the usual types of symptoms of tabes were determined. Still he did not think that the pathology of these cases was at all clear. There was little doubt, however, that a slight traumatism might form the point of origin where there already existed a family taint or a condition of the spinal cord favorable to the development of tabes. In the case cited by the author of the paper there were indications approaching traumatic tabes, and time might develop other symptoms of myelitic disease.

DR. E. D. FISHER admitted that the injury might have had its influence. The hereditary cases were likely to have a mixed form of spinal disease with motor symptoms of involvement of the posterior columns with the class of symptoms of sensory tabes. Such a case as the one reported might be looked upon as one of hereditary disease.

The CHAIRMAN said that while the suspicion of hereditary trouble in the author's case was great, still the traumatism was a factor which could not be overlooked and this, with the hereditary predisposition, might have acted as an exciting cause. The symptoms pointed to the myelopathic form of the disease, with fibrillar tremor and characteristic degeneration. They had all seen cases of progressive muscular atrophy which had begun in the leg without any hereditary history. With further observation of the case under discussion, the question could be tested whether

A BABY seldom sneezes nowadays without some fond and foolish person saying, "It has the grip."

the symptoms presented any new type of the hereditary form.

DR. KNAPP thought the question of sensory tabes in his case was hardly worth consideration, the occasional pains in the leg being the only sensory symptoms.

#### A CASE OF SPASTIC PARAPLEGIA. COMPENSATORY GAIT.

DR. BIRDSALL presented a child with a history of spastic paraplegia, which had supervened upon a severe instrumental delivery at birth. He had thought the case of interest because, while the child was only affected on the right side, which caused it to walk upon the toes of the affected foot, it had so adjusted the position of the other foot as to secure a kind of compensatory gait, which enabled it to get about with more or less facility.

DR. F. PETERSON said the case appeared to him to exhibit symptoms of a hemiplegia of one side, and of a crural monoplegia of the opposite side, which Dr. Birdsall considered was unaffected; in other words, it was a case of partial diplegia. There was certainly considerable adductor spasm with cross-legged position, and great exaggeration of deep reflexes of both sides with contractures of both feet, although more marked on one side than the other. He had seen a large number of cases of spastic paraplegia in which one arm was involved in addition to both legs, but without complete diplegia.

The CHAIRMAN thought that the child had sufficiently marked symptoms of diplegia, except that the left arm and the left leg were not much involved. The knee-jerks were exaggerated on both sides. It seemed to him that the difference between the two sides was that the contractures on the left side had relaxed, and that the child had consequently learned to use the leg a little better than the other.

#### CLINICAL AND PATHOLOGICAL OBSERVATIONS ON INJURIES OF THE CERVICAL SPINAL CORD.

This was the title of a paper by DR. C. A. HERTER. The histories of five cases of injury to the spinal cord were detailed. The first four were all examples of severe crushing; the fifth was an instance of injury to the cervical vertebra, with relatively slight damage to the nervous structures in this region. Among the most interesting features of these particular cases were their bearings upon the localization of the functions of the cervical cord. In Case I there was an upward extension of the motor paralysis, from the interossei and flexors of the fingers to the extensors of the fingers and wrists, the pronators and supinators, the triceps, biceps, and deltoids, successively. In Case II, the order of advance was much the same. In both cases the anaesthesia occupied the body and legs below a V-shaped line across the upper part of the chest and the inner half of the arms, forearms, and hands. While the motor symptoms progressed upwards in both cases, the area of anaesthesia made no advance. When the patients were first seen, they presented essentially the same motor and sensory phenomena, namely, weakness of the hand-muscles and the distinctive anaesthesia above mentioned. The cord-lesion was the same in both cases, that is, complete crushing at the eighth segment, and partial softening of the seventh and sixth segments. There was no doubt that the peculiar distribution of the anaesthesia was due to the crush of the

eighth segment. In both cases the bone lesion was a fracture-dislocation of the sixth upon the seventh cervical vertebra. In three of the four cases, there was pressure of the displaced or fractured vertebra upon the cord at the time of the operation or autopsy. In all total transverse lesions of the cord, and especially in those of the cervical and lumbar enlargements, certain symptoms were referable to the damage of the cord as a central organ, as opposed to those symptoms which depended on the obliteration of the functions of the cord as a conductor of impulses. These symptoms in the cervical region included loss of power and cutaneous sensibility, muscular atrophy, and degenerative electrical reactions. In two of the cases (IV and V) there were abdominal symptoms worthy of note. In each case, on the day after admission, the abdomen became tympanitic, and exceedingly tender to pressure, and repeated vomiting occurred, the vomitus having at one time a greenish color. The abdominal distention became very great, but began to subside, together with the pain and tenderness and vomiting, in the course of a few days. The temperature in cases of injury to the cervical cord varied much, according to the severity of the damage. The last feature of these cases to which it was desired to call attention was the state of the reflexes, especially that of the knee-jerks. The superficial reflexes (cremasteric, plantar, abdominal) were commonly lost from the beginning in cases of complete crush of the cord, but a day or two sometimes passed before they were all lost. If the patients survived for several days or a week, some or all of the superficial reflexes returned. In all four of the cases of complete crush of the cervical cord, the knee-jerks were abolished from a very early period after the accidents which caused these crushes, respectively. The motor and sensory paralyses below the level of the lesion were complete; and in all the termination was fatal. It might safely be concluded that when bilateral loss of the knee-jerks follows immediately upon a sudden lesion of the cervical cord, we had to deal with a case of extensive and total transverse damage to the cord, and that the patient would die from it. It was not urged, of course, that this diagnostic and prognostic sign should be used to the exclusion of other associated conditions. These considerations led to one important practical conclusion, namely, that cases of crush of the cord presenting complete or considerable paralysis of motion and sensation below the lesion, and associated with loss of knee-jerks, should not be operated upon.

DR. KNAPP said that the point brought forward by the reader of the paper upon the question of the inhibitory suppression of knee-jerk was of interest, as he had advanced the same idea many years ago. His case had been one of transverse myelitis, but not of traumatic origin. Entire absence of knee-jerk had been observed. Some weeks after, when the irritative processes had ceased in the lower portion of the cord, there were very pronounced exaggerations of the knee-jerks, with ankle and patella clonus.

DR. FISHER said it was a question whether, if the lesion was not destructive but simply of an irritative character, there would be a loss or an exaggeration of the reflexes. He thought that the irritation must be very severe indeed to give rise to loss of knee-jerk.

The CHAIRMAN said that the phenomena connected with the loss of knee-jerk were quite different in cases of chronic cervical injuries. Its sudden abolition was entirely restricted to these cases of traumatism.

DR. HERTER said that cases were on record of slow inflammatory processes resulting in loss of knee-jerk, but he had never seen such a case.

# THE NEW YORK ACADEMY OF MEDICINE. SECTION ON ORTHOPEDIC SURGERY.

STATED Meeting, December 19, 1890, V. P. GIBNEY, M.D., Chairman.

## THE NON-OPERATIVE TREATMENT OF DELAYED UNION IN FRACTURE OF THE LEG.

DR. JOHN RIDLON presented a paper upon this subject, illustrated by two cases.

The first patient, Thomas C. B., thirty years old, unmarried, gave no history of any constitutional disease. On March 22, 1888, while endeavoring to escape a passing team, he sustained a compound fracture of the right tibia in the lower third. The fracture was treated by a plaster-of-Paris dressing under the direction of a very well-known and skilful surgeon. The plaster splint was renewed from time to time, yet, on September 17th, when he was admitted to the Roosevelt Hospital, there was still slight motion at the seat of fracture, and Dr. Frank Hartley found on exposing the parts at the time of operation, that there was an oblique fracture of the tibia, passing from below upward. The space between the fragments was filled with a thin wedge-shaped piece of fibrous tissue. At the inner edge of the fracture, there was a thin line of bony union. The fragments were freshened, and then wired together, and the plaster dressing applied. He remained in bed for thirty-one days, but at the time of his leaving the hospital on October 22d, the union was not solid.

December 27th. He was transferred to Dr. Ridlon's care.

January 10, 1889. The plaster was removed. There was distinct antero-posterior motion, and soft union, but no callus could be felt. There was some tenderness on motion and pressure at the point of fracture. Only moderate constriction was made, as the dependent position after the removal of the plaster, caused abundant œdema. The patient was allowed to go out of doors at once. At the end of nine weeks, union was solid, and there was abundant callus. The patient said then that he had continued the use of the crutches for some time, but had removed the upper supporting part of the splint at the end of the third week, as it was uncomfortable. The lower portion of the splint which acted only as a lateral support, he continued to wear for about five months.

The other patient, Wm. D., twenty-two years old, was admitted to the New York Hospital on May 26, 1890, with a compound comminuted fracture of the right leg at the middle and lower thirds. The bones projected anteriorly through a large lacerated wound; there was much displacement and much contusion. Dr. W. T. Bull removed the loose fragments, and secured apposition and good drainage. A rise of temperature necessitated a change of dressing, and Volkman's splint was applied for three weeks, and after this, plaster-of-Paris splint with a fenestrum. Union was delayed. He was allowed to walk about on crutches and partly on the leg for two or three weeks prior to his discharge on August 5th, for insubordination. At this time, there was some deformity and he was still wearing the

plaster splint. When the patient came under Dr. Ridlon's care on September 22d, no callus could be felt, but there must have been soft union, as the fragments could not be displaced. The plaster splint was discontinued, and in its place, the caliper splint of Thomas of Liverpool was applied, being so modified as to prevent motion at the ankle. A laced leather sleeve was also added. A band buckled across the front just above the patella, prevents forward bending of the knee, and another band below the knee surrounds the leg and outer bar, and furnishes the means of obstructing the circulation to any desired extent. The leather sleeve adds to the patient's comfort, but care should be taken that it is not sufficiently tight to check the desired œdema. As a result of this treatment, solidification slowly, but steadily, took place, and an abundant callus was thrown out. At the end of nine weeks, no motion could be detected, and he could walk across the room without the splint or any support. After the application of the splint, the crutch was used only for a short time, and he was soon able to walk three or four miles without discomfort, and after eight weeks, he returned to his laborious occupation of unloading vessels.

These cases served to illustrate the treatment advocated by the author in cases of delayed union, which he was careful to distinguish from non-union, or pseudoarthrosis. The normal union of a fractured bone occupied a pretty definite period, and when delayed beyond this time, it was properly a case for non-operative treatment, whereas, such treatment was entirely inapplicable to cases of non-union. For delayed union, no cutting operation should be thought of until every other known means, and an abundance of time have been expended.

The present fashion of treating fractures by plaster-of-Paris bandages led to deficient immobilization, or else to constriction at the seat of fracture. The author thought no dressing had ever been devised for the treatment of fractures, which so poorly accomplished the end in view, that is, immobilization without undue compression. Good results were obtained with these dressings, but their proper use required greater skill and experience than any other dressing. If plaster were applied before swelling occurred, it prevented the formation of the normal amount of callus, and in a certain number of cases, resulted in delayed union. If applied after the occurrence of swelling, the dressing soon ceased to immobilize the part, and so not infrequently caused delayed union.

The treatment advocated by Dr. Ridlon was that employed by Hugh Owen Thomas, and in the words of that surgeon consisted in, "hammering, damming, depending, and fixing" the bones involved in the fracture.

The hammering may be done with or without an anæsthetic, and should not be repeated oftener than once in two weeks. Dr. Thomas at first made use of intermittent constriction, but in 1881, he employed continuous "damming," and resorted less to hammering. The constriction should be sufficient to cause abundant œdema, but not enough to cause pain, or interfere with the nutrition of the limb. The proper immobilization of the fracture is the most important element of treatment, and to do this, the bones must be held without producing constriction at the seat of fracture, the muscles covering the part must be kept at rest by continuous fixed traction, and not nagged by

elastic or intermittent traction, and the joints which are moved by these muscles, must be absolutely locked. When there is a fracture of the bones of the leg, the knee and ankle must both be locked, and it was on this account, that he had modified the caliper splint of Thomas in the way already described. This objection applied with even greater force to the well-known splint of Dr. H. H. Smith of Philadelphia.

DR. N. M. SHAFFER said that his experience with ununited fracture dated back to 1876, when he saw in consultation an ununited fracture at the junction of the upper with the middle third of the femur. The injury had been received about three months previous, and there was much overlapping. He applied pressure by means of a felt coaptation splint, and a traction apparatus, which allowed of the patient walking about with crutches. After a few weeks, he walked on the limb, with the traction splint, and in about three months, the parts were united. He had had since then three other cases of fracture of the shaft of the femur, which he had treated in the same manner, and with equally good results. He thought that the method advocated in the paper was not necessary, and that as much could be done by securing apposition of the fragments, direct pressure at the point of fracture by means of a coaptation splint, and the maintenance of the good position by the use of some traction apparatus. Change of climate also exerted a strong influence.

DR. A. B. JENSON thought that cases of this kind which had been treated by Dr. H. H. Smith, as well as some treated by the late Dr. E. D. Hudson, of this city, showed that the desired result could be obtained by the use of an apparatus which would permit the patient to walk around. Union was brought about under these circumstances probably by the friction, irritation, and congestion of the parts caused by the walking. Dr. Thomas's experience seemed to confirm this view, but the treatment by hammering, he considered cruel. He was reminded of a suit for malpractice which was brought against Dr. Garcelon, of Maine, on account of an ununited fracture. In order to excite sympathy in his behalf, the patient had applied a rough home-made apparatus, and had gone about the country in this way for some time previous to the trial; but when the case came to trial, it was found that union had taken place.

DR. S. KETCH spoke of a boy who had received a compound fracture of the femur, which, by injudicious treatment, had failed to unite. When he saw the case in consultation, the boy was suffering great pain, and partly with a view to relieving this, he applied a long traction splint without any coaptation splint. The pain was almost immediately relieved, and the local condition also improved, so that within a month, he was walking about on a hip-splint.

DR. R. H. SAYRE related his experience with a case of delayed union in a fracture of the leg, occurring in a syphilitic subject, who was also in the early stages of locomotor ataxia. He was a very heavy man, and there was a marked angular deformity. After irritating the ends of the bones by rather severe manipulation with the hands, he applied plaster-of-Paris, and renewed it from time to time, for six or eight months. During the first month, he used crutches, but after this, he was able to put the feet to the ground. At present, there is firm union of both bones. In this case, there was much oedema without the use of a constricting band, for the patient's heart and kidneys were in bad condi-

tion. Dr. Sayre thought that the hammering which the weight of the body produced upon the parts after they have been placed in position, was more efficacious than a hammering of the sides of the fragments by means of a mallet. He thought it quite possible, that too prolonged traction in cases of fracture of the femur, might be responsible for some of these cases of non-union, for, it was not improbable that more traction was often exerted than was sufficient to overcome the already tired muscles, and as a result, the bones were drawn too far apart to secure good union. He could not accept Dr. Ridlon's criticisms upon the use of plaster-of-Paris as a surgical dressing for fractures in general. If properly applied immediately after an injury, and after the parts were in proper position, they could be immobilized, and there would be very little swelling. The swelling was often due to obstruction of the circulation by the abnormal position of the bones.

DR. W. R. TOWNSEND spoke of a case which he had presented to the Surgical Section last year. The boy had fractured his femur at Seabright, and notwithstanding skillful surgical treatment, there was no union after three months. He was brought to the Hospital for Ruptured and Crippled in this city, and a long traction-splint was applied, which enabled him to go about. Walking around, together with the change of air, brought about speedy improvement; and after eight weeks, there was good union, and the apparatus was removed.

DR. C. A. POWERS said that a considerable number of cases of delayed union in fractured legs were yearly referred to him at the Out-Patient Department of the New York Hospital, after their discharge from the wards. It was his invariable custom to have them walk about with a light plaster-of-Paris splint, and his results had been uniformly good. He had certainly treated during the last year, six or eight such cases, and in no instance had it been necessary for them to return to the In-door Department on account of failure to secure good union. He was familiar with the history of Dr. Ridlon's second case, who was originally a patient in the New York Hospital. He believed that had this patient walked about without the application of a brace, he would most probably have obtained good union in about the same length of time. The delayed union in this case was distinctly due to the severe nature of the compound fracture, this being followed by suppuration and some necrosis. He thought the means advised by Dr. Ridlon excellent, yet braces of this kind were not easily within the reach of many country practitioners, and more convenient means would accomplish the same results. He could not understand Dr. Ridlon's strictures upon the use of plaster-of-Paris, and he heartily endorsed what Dr. Sayre had said on this subject. If deprived of the use of plaster-of-Paris, he would feel that he had lost the most valuable of all the means at his command for treating fractures of the leg or arm. Out of five or six hundred cases of fracture of the upper extremity, which had been under his care, there had been very few cases of delayed union which had not yielded to rubbing of the ends of the bone, blistering, or very light hammering, the latter not sufficient to cause pain. In two or three obstinate cases, the ends of the bones had been drilled; the patients were treated as out-patients, and with invariably good results.<sup>1</sup>

<sup>1</sup> He did not remember that he had ever been obliged to refer a pa-

DR. RIDLON, in closing the discussion, said that he thought the application of a snug plaster or other bandage lessened the amount of swelling, and that the less swelling, the less callus, and *vice versa*. There was no question about the efficiency of plaster-of-Paris when skillfully applied, but it was not always so applied, and he had seen very unpleasant results from its use. As regards the effect upon these cases, of walking about, he would say that his first patient walked around his room with a well-adapted plaster splint, for two-and-a-half months after the operation, without any gain in solidification; whereas, three days after beginning the treatment which he had described, the patient was able to walk some distance. The second patient had been walking around in the hospital with crutches, and after leaving there, continued to do so for about three months more before coming under his care. Under the new treatment, he was able to dispense with one crutch at once, and with the other very soon afterward, and at the end of eight weeks returned to his work. These two cases were, of course, not sufficient basis for any definite conclusions, but they were presented for the purpose of illustrating a plan of treatment not very commonly known or employed here.

DR. ROYAL WHITMAN presented a case of

FRACTURE OF THE NECK OF THE FEMUR, IN A CHILD, AGED SEVEN YEARS.

#### UNIFORM NOMENCLATURE IN ORTHOPEDIC SURGERY.

DR. W. R. TOWNSEND took this for the theme of his paper, which was as follows:

The object of writing this short paper is to elicit a discussion from the members of the Orthopedic Section of the Academy of Medicine upon a subject to which, of late, little attention seems to have been paid, yet to which much attention and time must be given, unless one is continually provided with a dictionary when reading; for, to read intelligently the medical literature of to-day, a study of etymology and synonyms is all-important, and even with this knowledge, we may still often be in doubt as to what disease is referred to, as some authors described somewhat different affections under the same name. The spondylitis of medicine is essentially different from the spondylitis of surgery. The former is a rheumatoid peri-arthritis, affecting chiefly the spinous processes and lateral masses, the inflammation encroaching on the foramina of exit, and producing various painful neuralgia; the latter is Pott's disease or tubercular osteitis of the vertebrae, etc.

Many reasons exist for this confusion and multiplication of terms. Many diseases were so inaccurately described at first, that the name suggested, could easily be improved upon, and later writers have done so, with a view of simplifying matters, and have thus increased our list of synonyms; again, popular terms or names that could be easily understood by the laity, have been introduced from time to time, until in some cases such terms have almost entirely superseded the more exact and scientific ones. Increased knowledge, such as the discovery of the tubercle bacillus, has caused us to classify some diseases as tubercular, just as we classify others as syphilitic, or malarial; and this list will probably be still further increased.

It is not my purpose to take any disease and weary you with a list of the different names it has gone by

from the earliest times to date, but will simply give several examples. In a recent work on Orthopedic Surgery, the same morbid process or disease, when it affects the spine, is known as Pott's disease; when affecting the hip or sacro-iliac joints, as hip disease; or sacro-iliac disease, when affecting the knee, as tumor albus; and in the case of the other joints, simply as ankle-joint or tarsal disease, etc. Of course, all, or nearly all, the other terms in common use are referred to, but it is under the above headings that the disease is described.

The hospital reports of the Roosevelt (New York), St. Luke's, Mt. Sinai, the Children's Hospital (Boston), the New York Orthopedic, and the Hospital for the Relief of the Ruptured and Crippled show this same variety of expression. In them we read of hip disease, hip-joint disease, tuberculosis of the hip, tuberculosis of the hip-joint, morbus coxae, chronic disease of the hip-joint, and osteitis of the femur. In other words, in seven different reports we have seven different names for the same disease. Other examples could easily be cited.

This multiplication of terms leads to confusion and much difficulty in actually arriving at a true idea of the relative frequency of any one disease, unless we thoroughly appreciate these facts; for who can say that the disease was of the same nature, when on one page we read of tuberculosis, on the next of caries, and the next of osteitis of the tarsus. Much of this variety and confusion of terms could very easily be avoided.

This problem, although presenting difficulties, seems to me ought to be discussed. Its solution depends simply upon the profession agreeing upon certain terms to describe certain diseases, and then strictly adhering to them. More care in diagnosis will result; a synovitis or arthritis will not be classified as an osteitis, and all the different diseases of the knee, for instance, will not be included under the terms, white swelling or knee disease.

DR. KETCH offered his congratulations to the author for the novel and interesting subject upon which he had written. He thought, however, that it would be very difficult to find one name which would cover the various conditions of disease found at the hip-joint. He agreed with the author of the paper that such terms as "tumor albus," and similar expressions, should be discarded.

DR. H. W. BERG thought pathology was at present too vague to admit of the use of a more exact nomenclature.

DR. R. H. SAYRE reminded the members that Dr. J. W. S. Gouley had devoted much time and labor in the preparation of an exhaustive work on medical nomenclature and classification of diseases. In it were mentioned terms which were very curious, although etymologically correct, and the profession would be slow to adopt such expressions. For instance, castration is spoken of as *orchietomy*.

DR. J. H. JENSON was of the opinion that there was no likelihood of any one being led astray by the present nomenclature, and other authors besides Dr. Gouley had expended much labor upon similar works, which were of doubtful utility.

DR. TOWNSEND, in closing, said that his paper had been misunderstood, for no question of pathology was involved. He had simply deprecated the use of so many terms to express one and the same condition.

gent to the hospital for operative treatment. He thought that similarly good results would follow this plan of treatment in most cases of delayed union in frac. ure of the leg.

**ARE ANATOMY AND PHYSIOLOGY LIBERAL STUDIES?**

At a recent meeting of the Board of Overseers of Harvard College a supplementary report of the Special Committee on Changes in the Academic Department and in its relations to the professional schools, was under consideration, and certain propositions offered by this Committee were voted on. Two of these propositions especially concerned medical education, namely:

That the Board of Overseers recommends the modification of the present Regulations of the College Faculty in accordance with the following proposition:

That a Senior intending to enter the Medical School and to take the full four-years' course therein may, under proper supervision, include in the requirements for the degree of Bachelor of Arts the courses on physiology and anatomy required in the first year of the Medical School, each of said courses to count as one full elective course.

That, in the opinion of the Board of Overseers, it is advisable that the Faculty facilitate the attainment of the degree of Bachelor of Arts, upon petition, in less time than four years, especially by those students intending to take professional or graduate courses of study, by any means which do not involve either a reduction in the number or difficulty of the courses required for the degree, or an undue hurrying of the students' work.

Both of these propositions were rejected by the Overseers, the former by a vote of five to eighteen, the President of the University voting in the negative, and the latter by a similar vote, the President voting in the affirmative.

It is not the province of this JOURNAL to question whether these proposals were voted upon strictly on their merits by the Overseers, or whether, owing to their relation to other proposals, regarded by some as kindred, they shared a common fate. It is, however, legitimate for it to speculate whether such a vote truly represent the tendency of thoughtful sentiment today among college-bred men and among our educated communities, in regard to professional studies and professional schools. We find it difficult to believe that it does.

The present relation of professional studies, and

especially of medical studies, to an academic course, is concisely given in a short article entitled: "Is the Study of Medicine a Liberal Education?" by Prof. D. W. Cheever, of the Harvard Medical School, published in our last issue. It is very difficult to comprehend the mental attitude of one who, in the latter part of the nineteenth century, is unable to regard such studies as anatomy, physiology, or constitutional law as, in the widest acceptance of the term "liberal" studies. Latin, Greek, Mathematics and Hebrew may equally be regarded as "bread and butter" studies for men who become teachers or clergymen. Chemistry and Physics and Political Economy are certainly such studies for a large number, if measured by any "illiberal" estimate.

The truth is, some way must be found to lengthen rather than to shorten professional education, and especially medical education. The medical graduate with an academic degree is already too old, and it is plain that if young men cannot be liberally educated on such studies as those we have mentioned, many of them, if modern social life follows its present directions, must be illiberally educated without some of those studies which have hitherto claimed the title of "liberal" by right of inheritance.

**MEDICAL MEN AND THE SECULAR PRESS.**

To what extent a medical man may properly allow his name and opinion to be published in the secular press, was discussed at a recent meeting of the Medical Society of the County of New York. The question has been more than usually prominent both in this country and in Great Britain since the beginning of the excitement caused by Koch's method; and many severe criticisms have been made of the code of ethics, on the one hand, and of so-called free advertising on the other. In order to obtain different opinions on the subject, a paper was read before the above-named Society by Dr. Frederick R. Sturgis, on March 23d, and discussed by those present, including a few laymen present by invitation. The general opinion seemed to be held that under certain circumstances it is unavoidable that medical opinion should be given to the public, and that it is impossible to frame a code of ethics which shall cover individual circumstances. What the conditions are under which a physician may allow himself to be quoted, and whether it is ever justifiable to seek publicity when personal gain may be expected from it, are questions which, as might be expected, brought out differences of opinion.

The reader, in summing up, gave as occasions in which a medical man might allow his opinion to be published: (1) When an opinion is sought on matters relating to public health; (2) with regard to new or unusual methods of treatment; (3) to correct a mistaken impression with regard to an operative procedure or method of treatment; (4) although not strictly pertaining to the subject, it is perhaps admissible for physicians to advertise their names in the daily press,

and that there would be no harm in stating the fact that one treated a certain class of diseases.

Another member thought that with rare exceptions, general questions could not be answered by a man to the satisfaction of his fellow-practitioners or of the interested public. If interviews were permitted the dignity of the profession would suffer from the absurd notoriety acquired by unscrupulous self-advertisers. He believed that the newspaper which would get a thoroughly informed medical man on its staff, would render a great service to the people. The editor of a daily paper, present by invitation, feared that the profession would soon be expressing loud complaints if daily papers had medical editors on their staffs. He thought there were at least three occasions when the public had a right to demand the opinions of medical men. One was when, like during the recent excitement regarding Koch's lymph, a new remedy was introduced which was likely to arouse the hopes of a large class of sick people. Another, when an epidemic made its appearance. Again, when a Grant, a Sherman, or a Garfield was lying on his death-bed and a reverent people looked to the profession for words of hope, or to be prepared for the end of all hope. He thought the line which separated the reputable physician from the advertising quack was not so tenuous that the public would not distinguish the blatant advertising of the latter from the conscientious interview with the former, which an interested public now and then demanded.

It was suggested that the Committee on Hygiene of the Society might be deputed to be the channel of communication between the profession and the public.

The editor of an esteemed medical contemporary said that there were two ways of medical interviewing in the daily press; a proper one and an improper one. The proper one was for the individual to speak for his profession, to sink the *ego* entirely out of sight and be proud to be spokesman for his brethren to the public. If that plan were carried out he believed we need never be ashamed of any interview which appeared in the daily press. The improper way was to magnify the *ego*, by placing the profession in the background and making it appear that by some special skill of our own we were superior to our associates, thereby creating invidious distinctions. It was often for want of manly and out-spoken views on behalf of the profession that legitimate medicine suffered in the eyes of the people, and not infrequently courted the criticism of the secular press. The great trouble had been, however, in using covert means to advertise self by countenancing the reports of surgical operations, special methods of treatment, and the like. He could testify to the fairness and desire for truth of representatives of the press, and had often been surprised at the amount of knowledge which they had shown of medical subjects.

The whole subject seems to us a very easily debatable one, in regard to which it would be easier to form an opinion if all doctors were judicious and altruistic, and all reporters discreet, and not under bonds to

furnish copy. It takes more self-abnegation or more experience than can be expected from the average citizen, either with or without a medical education, to cope with the sometimes too nimble reporter.

#### THE SEAT OF CUTANEOUS SENSATIONS.

THE seat of cutaneous sensations, tactile, thermic, pathic, was located by Ferrier in the gyrus hippocampi and gyrus fornicatus. This was the result of observation of experimental facts, where, in monkeys, the hippocampal region on one side was more or less extensively destroyed; during life the animal manifested impairment or abolition of sensibility on the opposite side of the body. The subject was afterwards investigated by Gerald, Geo. Schäfer and Victor Horsley, who corroborated Ferrier's results. In the last edition of the "Functions of the Brain," Ferrier maintains the same doctrine. Other investigators, notably, Exner, Petrina, Hitzig, Munk, Nothnagel, Schill, Goltz, Trepier, basing their opinions on facts where the loss of cutaneous sensibility has accompanied paralysis of motility due to lesions of the motor region of the cortex, have been inclined to regard the motor and sensory centres as identical; and Dr. C. L. Dana has summed up many of these observations along with cases of his own in a late number of the *Journal of Nervous and Mental Diseases*. A study of these cases convinces this writer that the sensory centres for special parts of the body, that is, face, arm, leg, are in general the same as the motor centres for those parts, but are larger and more diffuse. The tactile sensation seems to be more strictly confined to the motor areas.

From Dr. Dana's summary it appears that tumors and slowly growing lesions in the motor areas, either in or just below the gray matter, produce paræsthesia and slighter degrees of anæsthesia. Softening, thrombotic or inflammatory, of the same areas, coming on suddenly, produces localized anæsthesia if it is extensive, and completely destroys the parts. Pressure clots from meningeal hæmorrhage, if extensive and severe, will cause partial anæsthesia of the opposite side, as well as profound hemiplegia. There is no known region of the cortex, lesion of which will cause anæsthesia without accompanying hemiplegia. It is not possible for a cortical lesion to cause total unilateral anæsthesia without the lesion being so extensive as to be rapidly fatal. In fact, Dana lays down a law that "cutaneous anæsthesia of organic cortical origin is always limited to, or more pronounced in certain parts, for example, the face, or arm, or lower limb of the body, and is generally incomplete."

There are numerous interesting observations on record which sufficiently suggest the intimate association of motricity and cutaneous sensibility in the cortex. The case of Huguenin<sup>1</sup> is instructive in this regard. The patient was a woman, forty-six years of age, who had an organic affection of the valves of the heart. A sudden loss of consciousness was attended

<sup>1</sup> Cited by Nothnagel.

with slight convulsive movements in the right half of the face and in the right arm. To these phenomena succeeded the following symptoms, lasting till death, which occurred three months later: Paresis of the right limbs, paralysis of the hypoglossus and of the inferior branches of the facial on the right side; paresis of sensibility of all the right half of the body including the trunk and the face; marked lessening of sensibility to pain; almost entire disappearance of the thermic sense; pronounced aphasia; right hemipia. The autopsy showed obstruction of the left Sylvian artery and necrosis of the posterior extremity of Broca's convolution, of the inferior portion of the two ascending convolutions, of the anterior part of the inferior parietal lobule and of the upper parts of the little fan-shaped convolutions of the insula. In one of Vetter's patients where the autopsy revealed a glioma with red softening of the cortex of the principal motor regions, there was diminution of the muscular sense and hemianæsthesia of the skin.

Dana (*loc. cit.*) affirms that no amount of scrutiny can explain away the numerous cases in which superficial cortical lesions have caused monoplegias and monoanæsthesias, and shows that the anterior part of the frontal lobes, the occipital and temporo-sphenoidal lobes are latent regions so far as cutaneous sensory disturbances are concerned. If then, says this writer, we can exclude this gyrus fornicatus and hippocampus, nothing is left as centres for these sensations but the central and the parietal lobes. He reports three cases coming under his own observation which seem to present positive evidence that the sensory and motor areas are identical.

Doubtless, the only satisfactory way of studying this vexed question is by supplementing clinical and pathological experimentation with experiments on animals, and deciding according to the weight of probability. An attentive reading of Ferrier's recent Croonian Lectures is likely to leave on the mind the impression that in respect to the localization of the centres of general sensation he has scarcely done justice to the careful observations of Dana, Exner, Luciani and Seppili, Starr and others. He speaks of the evidence in general as "unsatisfactory," "the lesions having been microscopic specks of themselves insufficient to cause anything (sic)," "and for the most part tumors which may cause anything, or multiple foci of disease not confined to the cortex itself." This certainly does not seem to be quite a fair representation of the cases reported by the above mentioned authors.

Dr. Ferrier affirms that "in an independent investigation of recorded cases he finds that out of 110 cases of general lesion of the Rolandic zone, only 21 were noted as showing any loss of sensibility. In one of the cases a large portion of the motor cortex was excised without any loss of sensation. . . . In another, there was general hyperæsthesia, more marked in the paralyzed side. In one, all varieties of sensibility were retained, but localization of touch was somewhat defective. Of five cases of excision of the motor cortex for focal epilepsy, in two reported by Von Bergmann

and Keen, sensation was intact. Of thirty cases of bronchial monoplegia, sensibility was unimpaired in twelve, not mentioned in fifteen, and affected in three." He thinks that in cases where some impairment was noted, the lesion was not confined to the Rolandic zone, but implicated adjacent parts, the sensory centres in the gyrus fornicatus, the hippocampus or the sensory tracts of the internal capsule.

It is evident that the question demands further investigation, and cannot yet be considered as settled.

#### MEDICAL NOTES.

**INFLUENZA.**—Reports of more or less severe outbreaks of epidemic influenza have recently been increasing. The condition in Chicago appears to be as serious as ever. Brooklyn seems to have suffered a little later than New York. In England, especially in Sheffield, it is on the increase, and more recently comes the same report from London.

**A PROPOSED INTERNATIONAL AMERICAN MEDICAL CONGRESS.**—Dr. Charles A. L. Reed of Cincinnati, purposes introducing at the Washington meeting of the American Medical Association resolutions to the effect that an invitation be issued to the medical profession in the various countries of North and South America to hold a congress in the United States.

**SCARCITY OF COD-LIVER OIL.**—According to the *Medical Record* there is likely to be a cod-liver oil famine during the coming year. The number of fish taken in Norway this season has not been more than one-eighth of the average quantity, and the oil, which could be bought last year at \$10 per barrel, now costs \$30.

**OSSIFIED MAN BROKEN.**—An ossified man who had been on exhibition in a museum, rolled out of his litter and down a flight of stairs in New York, breaking his legs and a finger. He is reported to be a veteran in his profession, having gone into the business when the ossified man industry was first organized.

**VIRCHOW STRASSE.**—The German Emperor has ordered that the street at the back of the Friedrichshain Hospital in Berlin shall in future bear the name of Professor Virchow, to whose untiring exertions the hospital in large measure owes its existence.

**NEW MEDICAL LAW OF ALABAMA.**—The penalty bill, as it passed the legislature, provides that any person practising medicine or surgery in that State without having first obtained a certificate of qualification from one of the authorized Boards of Medical Examiners of the State, shall be guilty of a misdemeanor, and on conviction thereof, shall be fined not less than twenty-five dollars nor more than one hundred. Provided, that this act shall not apply to any doctor practising medicine in Alabama who is a graduate of a reputable medical college, and who has complied with the law by having his diploma recorded by the judge of Probate in the county in which he is practising.

**PARKIN PRIZE, ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH.**—The late Dr. John Parkin, Fellow of the Royal College of Physicians, Edinburgh, left a bequest of one hundred pounds sterling for the best essay "On the Curative Effects of Carbonic Acid Gas or other forms of Carbon in Cholera, the different Forms of Fever, and other Diseases." The prize is open to competitors of all nations. Essays intended for competition must be written in the English language, and must be received by the Secretary, Dr. G. A. Gibson, not later than December 3, 1892. Each essay must bear a motto, and be accompanied by a sealed envelope bearing the same motto outside and the author's name inside. The successful candidate must publish his essay at his own expense, and present a printed copy of it to the college within three months after the adjudication of the prize.

**DEATHS UNDER CHLOROFORM.**—Recently, hardly a week has passed without at least one death being reported as having occurred under chloroform, in one of the countries in which it is in common use. The cases reported probably are but a small proportion of those which occur, and it is, of course, impossible to say whether there is an actual increase in mortality from its use, or whether more attention is paid to the subject on account of the work of the Hyderabad Commission. In some cases the theory that the respiration is primarily affected is not borne out. In a recent case reported in the *Indian Medical Gazette* there seems to be no doubt that the heart suddenly and permanently stopped after a small amount of the drug.

**SUIT AGAINST A DISPENSARY PHYSICIAN.**—A dispensary physician has been sued in New York by a patient suffering from abortion, on the ground that the physician, after making three visits, failed to visit the patient again, whereas medical attention was necessary for her. The defense stated that the physician had given notice that he was going out of town, a question of fact which was left to the jury, and also that the patient had refused to stay in bed as ordered.

In charging the jury the judge said in reference to the fact that the patient paid nothing for medical attendance, that this, in no respect, qualifies the liability of the defendant. Whether the patient be a pauper or a millionaire, whether he be treated gratuitously or for reward, the physician owes him precisely the same measure of duty and the same degree of skill and care. He may decline to respond to the patient, unable to compensate him, but if he undertakes the treatment of such a patient he cannot defeat a suit for malpractice, nor mitigate a recovery against him upon the principle that the skill and care required of a physician are proportioned to his expectation of pecuniary recompense. He also charged the jury to determine whether the injuries to the patient were the result of the abortion or to the lack of care of the physician, and said: "A physician does not contract to cure a patient. He is not an insurer, but his undertaking is only, and the duty which the law imposes on him is only, to exercise due skill and due care in the treatment

of his patient. The law exacts of a physician in the treatment of a patient, that reasonable degree of skill and that reasonable degree of care, which is ordinarily possessed and exercised by the profession, and he is liable in damages only for injuries resulting to the patient from the lack of either of these requisites. It is enough if a competent physician exercises his best judgment in a case." The jury gave the plaintiff sixty dollars.

#### BOSTON AND NEW ENGLAND.

**MEASLES.**—During the month of March, 447 cases of measles were reported in Boston, against 25 cases in March, 1890.

**THE BRISTOL NORTH DISTRICT MEDICAL SOCIETY** had its annual meeting April 16th. The following were elected officers for the current year: President, F. A. Hubbard; Vice-President, E. F. Galligan; Secretary, William Y. Fox; Treasurer, J. B. Murphy; Librarian, Martha Perry; Commissioner on Trials, C. Howe; Censors, Drs. Perry, Rogers, Round, Fox and Baker; Councillors, W. S. Robinson, A. S. Deane, S. D. Presbrey, J. W. Battershall and J. P. Brown.

**DIAGNOSIS OF SMALL-POX.**—The State Board of Health of Connecticut say, in their report for March, in regard to the prevalence of small pox, that one source of danger may be in consequence of the present rarity of its occurrence. There are physicians who have been in practice for several years who have never had an opportunity of seeing the disease, and hence fail to recognize it when it occurs in a modified form. Only a little over a year ago the disease gained an extensive footing in Meriden from the inexperience of the health authorities and their inability to recognize varioloid in a case which they called chicken-pox. There have recently been two cases in the State. The first was brought from Texas. A returned soldier came home soon after some children in the family had an eruption which was diagnosed as chicken-pox. From these children the case of small-pox was believed to have been contracted, the supposed chicken-pox probably having been varioloid. The other case was reported in Waterbury, and originated as it so commonly does, in the rag department of a paper mill.

**REPORT OF THE BOARD OF HEALTH OF CONCORD, N. H.**—In its annual report for 1890, the Concord, N. H., Board of Health congratulates the city upon the satisfactory condition of the public health. Thirty-eight cases of contagious disease were reported with seven deaths, including seventeen cases of typhoid fever with five deaths. In speaking of the outbreak of typhoid fever at Lowell and Lawrence, the Board says that although they believe it was conceded that the original influence was not to be found in New Hampshire, nevertheless, the investigations that were made to locate the primary influence that developed the epidemic, only served to show that such conditions may arise at any time, and therefore we should not be surprised should a demand be made to prevent the pollution of the Merrimack. In view of the possibility of such an attempt being made to prevent the

pollution of naturally clear and healthful water, it may be an act of wisdom for Concord and other cities in New Hampshire, which are now turning their sewage and refuse matters into the river, to be making investigations into the systems that contemplate the destruction of waste and effete material, and its economical disposal without being a nuisance to those in its immediate vicinity.

#### NEW YORK.

**SCHOOL OF BIOLOGY.**—Henry F. Osborn, D.S., Professor of Comparative Anatomy in Princeton University, has been called to Columbia College as head of the recently organized school of biology; though he has not as yet decided whether to accept the position. Prof. Osborn is a graduate of Princeton, class of 1877. After his graduation he went to England and studied under Adam Sedgwick, at Cambridge, and afterwards under Huxley and Howes. On his return he received the degree of Doctor of Science, and in 1882 was appointed to the professorship at Princeton.

**CARBOLIC ACID POISONING.**—At the Seney Hospital in Brooklyn, a nurse recently gave a young child suffering from marasmus, a dose of strong carbolie acid solution by mistake, for cod-liver oil, with the result of producing death. A coroner's inquest was held in the case, and in accordance with the recommendation of the jury, the nurse has been relieved from duty at the hospital.

**EXAMINATION OF IMMIGRANTS.**—Dr. John Godfrey, of the United States Marine-Hospital Service, has been assigned to duty in the Emigration Bureau; so that there will now be three physicians for the examination of arriving immigrants.

**SMALL-POX IN NEW YORK HARBOR.**—The yacht *Alca*, with Mr. W. K. Vanderbilt and other gentlemen recently arrived in New York with small-pox on board. As the case was well isolated on the voyage, the party were allowed to land, the yacht being detained at quarantine. The North German Lloyd steamship *Fulda* arrived from Bremen with a case of small-pox. The vessel and steerage passengers were detained.

### Miscellaneous.

#### EHRLICH'S TEST.

DR. CHARLES E. SIMON<sup>1</sup> gives directions for the proper application of this test, and concludes that it is of greater value in diagnosis than its present lack of popularity would indicate. The test consists of two solutions: (1) A saturated solution of sulphanilic acid in five per cent. hydrochloric acid; and (2) a one-half per cent. solution of sodium nitrate. These are to be mixed, just before use, in the proportion of 10 c.c. of (1) to 1 c.c. of (2). If this mixture be added to urine from a case of typhoid fever, the further ad-

dition of ammonia will produce a play of colors varying from an eosine rose to a deep garnet red. The most convenient method of applying the test is to take a few c. c. of urine in a test-tube, adding an equal quantity of the sulphanilic acid mixture, and shaking thoroughly; one c. c. of ammonia is then run carefully down the side of the tube. At the junction of the two liquids, there will be observed a ring of the characteristic color. In typhoid fever a color occurs upon the addition of ammonia, which may vary from an eosin to a deep garnet. As to the color-play which occurs in different kinds of urines, it will be observed that normal, or pathological, but non-febrile, urine remains either unaffected or its color is merely intensified by the addition of the ammonia; a deep orange tint may even be produced in this way, but has no significance whatsoever, and is easily enough distinguished from the typical color. The author concludes that the reaction may be obtained in typhoid fever from the fifth to the twenty-second day of the disease. Its absence from the fifth to the ninth day indicates a very mild attack, save in children, although this rule is not an absolute one. As it occurs previous to the appearance of the rash, it is a very useful aid in the diagnosis of typhoid fever.

#### PATHOLOGY OF GRIEF.<sup>1</sup>

THAT severe mental distress or fright sometimes produces physical disease, and occasionally even death, is an admitted fact, although the way in which it acts has hitherto been but little studied. In order in some measure to supply the deficiency in our knowledge regarding this matter, Dr. G. Bassi has recently made a number of observations on animals which apparently died in consequence of capture. Birds, moles, and a dog which had succumbed to conditions believed by Dr. Bassi to resemble those known amongst human beings as acute nostalgia and a "broken heart" were examined post-mortem. Generally there was hyperæmia, sometimes associated with capillary hemorrhages of the abdominal organs, more especially of the liver, also fatty and granular degeneration of their elements, and sometimes bile was found in the stomach with or without a catarrhal condition. The clinical symptoms were at first those of excitement, especially in the birds, these being followed by depression and persistent anorexia. The theory suggested by Dr. Bassi is that the nervous disturbance interferes with the due nutrition of the tissues in such a way as to give rise to the formation of toxic substances—probably ptomaines— which then set up acute degeneration of the parenchymatous elements similar to that which occurs in consequence of the action of certain poisonous substances such as phosphorus, or to that met with in some infectious diseases. In support of this view, he points out that Schule has found parenchymatous degeneration in persons dead from acute delirium, and that Zenker found hemorrhages in the pancreas in persons who had died suddenly; he refers also to some well-known facts concerning negroes in a state of slavery and to the occasional occurrence of jaundice after fright. He hopes that these hints may induce medical officers of prisons and others to study both clinically and anatomically this by no means uninteresting and unimportant subject.

### PREScriptions.

COMBINATION OF PARAFFIN WITH LANOLIN. — Paschkis<sup>1</sup> has found that the special advantages of lanolin are increased when diluted with paraffin. The formula which he found best for a basis is :

R	Lanolin . . . . .	.66 parts.
	Liquid paraffin . . . . .	6 parts.
	Ceresin . . . . .	1 part.
	Distilled water . . . . .	.65 parts. M.

A MIXTURE FOR HÆMOPTYSIS. — Bamberger<sup>2</sup> is said to have approved of the following mixture in hæmoptysis :

R	Turpentine	}	.	.	.	āā	3	j.	
	Oil of sweet almonds								
	Mucilage of acacia	}	.	.	.	.	āā	3	iv.
	Simple syrup								
	Distilled water	.	.	.	.	.	3	v.	M.

One teaspoonful of this mixture may be given every half-hour.

COPPER IN CHLOROSIS. — Liégeois<sup>8</sup> has obtained very satisfactory results in chlorosis from the following formula, suggested by Luton:

R	Cupri acetatis neut.	.	.	.	.	gr. $\frac{1}{2}$	
	Sodii phosphat. cryst.	.	.	.	.	gr. $\frac{1}{2}$	
	Pulv. glycyrrhizæ	}	.	.	.		
	Glycerinæ	}	.	.	.	aa q. s.	M.
	Ft. pil. no. i.						

One or two pills before eating, noon and night.

Deaths reported 3,984: under five years of age 1,340; principal infectious diseases (small-pox, measles, diphtheria and croup,

diarrhoeal diseases, whooping-cough, erysipelas and fevers) 455, acute lung diseases 1,075, consumption 370, diphtheria and croup 123, diarrhoeal diseases 78, scarlet fever 73, typhoid fever 62, whooping-cough 46, measles 36, cerebro-spinal meningitis 14, erysipelas 12, malarial fever 10.

From typhoid fever Chicago 25, Philadelphia 20, Brooklyn, Boston and Cincinnati 4 each, New York 2, Washington, Portland and Lowell 1 each. From whooping-cough New York 20, Brooklyn 12, Philadelphia 4, Chicago and Boston 3 each, Washington 2, Nashville and Cambridge 1 each. From measles New York 18, Chicago 11, Brooklyn 3, Washington 2, Boston and Cambridge 1 each. From cerebro-spinal meningitis New York 5, Cincinnati 3, Chicago and Washington 2 each, Philadelphia 1. From scarlet fever New York 6, Boston 3, Brooklyn 2, Chicago 1. From malarial fever Brooklyn 5, New York 3, Philadelphia 2.

In the twenty-eight greater towns of England and Wales with an estimated population of 10,610,426, for the week ending April 4th, the death-rate was 22.4. Deaths reported 4,304: acute diseases of the respiratory organs (London) 489, measles 184, whooping-cough 149, scarlet fever 35, diarrhoea 34, diphtheria 33, fever 30, small-pox (London 2, Bristol 1) 3.

The death-rates ranged from 14.1 in Derby to 36.5 in Hull, Birmingham 18.1, Brighton 14.5, Bradford 18.2, Leeds 27.2, Leicester 25.4, Liverpool 22.9, London 20.9, Manchester 26.9, Nottingham 17.6, Sheffield 21.7, Sunderland 22.2.

In Edinburgh 23.9, Glasgow 30.2, Dublin 23.9.

## METEOROLOGICAL RECORD.

For the week ending April 11, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM APRIL 11, 1891, TO APRIL 17, 1891.

By direction of the Acting Secretary of War, the leave of absence granted Captain HENRY P. BUNNINGHAM, assistant surgeon, in Special Orders 39, March 13, 1891, Department of the Columbia, is extended one month. S. O. 81, Par. 2, Headquarters of the Army, A. G. O., Washington, April 10, 1891.

By direction of the Acting Secretary of War, leave of absence for six months, on surgeon's certificate of disability, is granted Major PASSMORE MIDDLETON, surgeon. S. O. 81, Par. 4, Headquarters of the Army, A. G. O., April 10, 1891.

By direction of the Secretary of War, a Board of Medical Officers, consist of Major HENRY McELDERLY, surgeon, Captain JAMES C. MERRELL, assistant surgeon, Captain W. FITZMAUGH CARTER, assistant surgeon, is appointed to meet at West Point, N. Y., May 1, 1891, or as soon thereafter as practicable, to examine such cadets of the United States Military Academy as have been granted leave of absence until that date on account of physical disability, and to report upon their physical fitness to continue with the Corps of Cadets. S. O. 83, Par. 2. A. G. O., Washington, April 13, 1891.

By direction of the Secretary of War, the following changes in the stations of medical officers are ordered: Captain MASHALL W. WOOD, assistant surgeon, is relieved from duty at Fort Meade, South Dakota, and will report in person to commanding officer, Fort Preble, Me., for duty at that post, relieving Captain WILLIAM E. DAVIS, assistant surgeon. Captain DAVIS, on being relieved by Captain Wood, will report in person to the commanding officer, Fort Clark, Tex., for duty at that station. S. O. 85, Par. II, A. G. O., Washington, April 15, 1891.

# OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING APRIL 18, 1891.

GROVE S. BEARDSLEY, medical director, appointed a delegate to represent Medical Department of the Navy at meeting of American Association at Washington, D. C., May 8th.

JAMES M. FLINT, surgeon, appointed a delegate to represent Medical Department of the Navy at meeting of American Medical Association at Washington, D. C., May 8th.

S. H. GRIFFITH, passed assistant surgeon, detached from the U. S. S. "Dolphin," and granted one month's leave of absence from date of detachment.

## SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. — A regular meeting of the Society will be held on Monday, April 27, 1891, at the Medical Library, 19 Boylston Place, at 8 o'clock P. M.

Readers: Dr. J. W. Elliot, "Two Cases of Early Excision of the Vermiform Appendix"; Dr. W. H. Baker, "Small Subserous Fibroid of Uterus the Occasion of great Intolerance of the Bladder." G. G. SEARS, M.D., Secretary.

THE MISSISSIPPI VALLEY MEDICAL ASSOCIATION will hold its seventeenth annual session at St. Louis, Wednesday, Thursday and Friday, October 14, 15 and 16, 1891. A large attendance, a valuable programme and a good time are expected. The members of the medical profession are respectfully invited to attend.

E. S. MCKEE, M.D., Sec'y, 57 W. Seventh St., Cincinnati.

## ORGANIZATION OF THE HARVARD MEDICAL SCHOOL ASSOCIATION.

Boston, April 15, 1891.

A meeting of the 610 graduates of the Harvard Medical School, who have responded to our recent circular, will be held at the Boston Medical Library, 19 Boylston Place, Boston, on Thursday, April 30, 1891, at 11:30 A. M., to organize the Harvard Medical School Association.

J. R. CHADWICK, Chairman.

L. R. STONE, of Newton. H. F. BOWDITCH, of Worcester. G. E. FRANCIS, of Worcester. F. H. BROWN.

## SEVENTH INTERNATIONAL CONGRESS OF HYGIENE AND DEMOGRAPHY. SECTION OF PREVENTIVE MEDICINE.

The following arrangements have already been made: August 14th, after a short address by the President, a discussion will be held upon, "The Mode of Preventing the Spread of Epidemic Disease from One Country to Another"; opened by Surgeon-General McNab Cunningham, C.S.A., of London. August 15th, a discussion upon, "Diphtheria, with Special Reference to its Distribution and to the Need for Comprehensive and Systematic Enquiry into the Causes of its Prevalence in Certain Countries, or Parts of Countries, with a View to its Prevention"; opened by Dr. Edward Seaton, of London. August 16th, a discussion upon, "The Relation of Alcoholism to Public Health, and the Methods to be Adopted for its Prevention"; opened by Sir Dyce Duckworth, LL.D., M.D., of London, and by Professor Westergaard, of Copenhagen. August 16th, papers on miscellaneous subjects will be read and discussed. A list of papers accepted by the Section will be published later.

Gentlemen who are desirous of joining the Congress and taking part in any of the above discussions, or of communicating papers on other subjects within the scope of the Section, are requested to inform the honorary secretaries of the Section not later than June 15th. Abstracts of papers to be read in the Section must be furnished to the honorary secretaries not later than June 15th, and the full text of the papers before July 15th. Abstracts of papers should not exceed five hundred words, and should be typewritten, to ensure accuracy of printing and translation. Papers and abstracts may be written and speeches in the meeting delivered in French, German or English. No paper will be received which has been previously published or communicated to any other society. A limit of fifteen minutes will be fixed for a paper or speech introducing a subject, and a limit of ten minutes for all subsequent speeches or papers on the same subject.

Communications to the Section should be addressed to Dr. T. LEAVER, C.E.S., 10 Curzon Street, London, W. Those relating to the general business of the Congress should be sent to the Hon. General Secretary, at the offices of the Congress, 20 Russell Square, London, W.

## DEATH

GEORGE F. MASON, M.D., died on New York, April 15th, aged forty.

## OBITUARY. PRESTON SHELDON, M.D., M.M.S.S.

Dr. Preston Sheldon, who died at Wakefield, Mass., April 17th, of pneumonia, after a very brief illness, was born in New York City in 1853. He graduated at Middlebury College in 1874, and at the College of Physicians and Surgeons of New York in 1877, after having spent a year under the preceptorship of Dr. C. L. Allen of Rutland, Vt. He afterward spent two or three years of professional study in the schools of Vienna, Berlin and London, and after returning home devoted a year to the study of microscopy as applied to medicine. His professional training was unusually thorough.

After a brief period of practice in Brooklyn, N. Y., he came to Wakefield, and established himself there in 1883. His faithful application to the duties of his profession, and his excellent qualities of mind and heart, soon won for him the confidence of the community in which he lived. To him medicine was not a mere business or occupation, but a high and noble calling which he honored by a consistent and useful life. In the sick-chamber he manifested those traits which mark the successful practitioner. He not only showed a remarkable familiarity with progressive therapeutics in the treatment of the sick, but he omitted nothing which pertained to those minor, but very important, duties, embracing the details of good watchful care and nursing.

Not the least among his excellent qualities were his social and literary attainments, for he was a man of broad and liberal culture. The schools, the Public Library, and all important movements pertaining to the welfare of the town found in him a true friend and patron. Frequent, severe and long-continued attacks of illness impaired his health, interfered with professional labor, and undoubtedly made the final issue more certain. He struggled bravely with the insidious invader of health, and to an outward observer, in the intervals of comparatively good health, he invariably maintained an appearance of unusually robust and manly vigor.

## OBITUARY. AUGUSTUS PURDY WILLIAMS, M.D.

Dr. Augustus Purdy Williams died, on April 14th, after a long illness. He was born in New York City in 1858, and was educated at Columbia College and the College of Physicians and Surgeons. At the outbreak of the war he entered the naval medical service, and was appointed to the ship *Monticello*. After six months, however, he was transferred to St. Aloysius Hospital in Washington, and later he was placed in charge of the Clifton Barracks Hospital, at Elmdenburgh Hospital, where he remained until the close of the war. He next practised in New York for a few years, and in 1870 went to Rutland, N. J., where he built up a large practice, and remained until three years ago, when ill health forced him to retire from his profession. Of late he had resided in New York.

## OBITUARY. JAMES K. THACHER, M.D.

Dr. James K. Thacher, Professor of Physiology in Yale University, died, April 20th, of pneumonia, aged forty-three years. He was a son of the late Professor Thomas A. Thacher, and graduated at Yale College in the class of 1868, and from the medical department in 1870. His investigations in the comparative anatomy of fishes in 1877 gave him a wide reputation. He has had charge of the medical work in the "Century Dictionary." He was a member of the New Haven Board of Health, and physician to the Connecticut State Hospital.

## BOOKS AND PAMPHLETS RECEIVED.

Extract from Remarks made before the State Sanitary Convention at Pittsburgh, May 29, 1890, by Benjamin Lee, M.D., Secretary State Board of Health of Pennsylvania.

The Physical Diagnosis of the Diseases of the Heart and Lungs and Thoracic Aneurism. By D. M. Cantrann, B.A., M.D. New York and London: G. P. Putnam's Sons. 1891.

## Original Articles.

CEREBELLAR TUMOR; OPERATION; HÆMORRHAGE FROM DEFECT OF OCCIPITAL BONE; DEATH; GENERAL REMARKS.<sup>1</sup>

BY W. N. BULLARD, M.D. AND E. H. BRADFORD, M.D.

The patient, a girl, six and one-half years old, was first seen at the Out-patient Department of the Children's Hospital in April, 1890. At this time the mother gave the following history. The family history was entirely negative, except that an uncle on the mother's side had died when ten years old of brain fever.

For a year the patient has been subject to attacks of vomiting preceded by dizziness, when she runs to some piece of furniture or something which she can hold to for support. These attacks occur on an average, three times a week, but sometimes come as often as twice a day. Last Christmas (1889), she had the grippe and since then she has never seemed as well as previously. For six weeks, has been gradually losing power in the right lower extremity. No pain. No incontinence. No other symptoms.

The condition found at that time was as follows: Muscular development, fair, head appears rather large. The measurements were: circumference 50.25 cm.; glabella to inion 36 cm.; antero-posterior diameter, taken by pelvimeter, 18.50 cm.; biparietal diameter, taken by pelvimeter, 15.75. The chest circumference was 56 to 57.50 cm. Pupils dilated somewhat; react to light. Heart negative. Spine normal. Lower extremities seem alike. No atrophy. No vaso-motor disturbance. Sensation normal. Knee-jerks good. Gait unsteady, staggering.

Was recommended for admission to the hospital.

April 28th. Mother now states that three weeks ago patient began to lose use of the right upper extremity, but that this varied somewhat from day to day. Yesterday, began to lose use of the left upper extremity, and for the first time could not feed herself. Two weeks ago began to have pain in the back, and at times could not bear to have her back touched. Passes very little urine, and that with great difficulty. To-day passed only about a wineglassful, and that took ten minutes.

*Present condition.* Can move both upper extremities; grasp fair; nothing abnormal in their appearance. Admitted to hospital, service of Dr. Bradford.

May 1st. Has shown no decided evidence of affection of the upper extremities. Urine scanty; 1,015; acid; very slight trace of albumen; abundance of cells, some with one nucleus, some with two or three, single or in clumps.

May 3d. Had an attack of vertigo this morning, and fell. Inco-ordination of lower extremities; cannot move foot in a circle.

May 9th. Examination of the eyes by Dr. Wadsworth. Hypermetropia; papillitis o. n., worse right. Another attack of vertigo this morning.

No arsenic or lead in the urine.

May 17th. Nausea; staggering; almost totally blind. Transferred to medical department for treatment with mercury.

June 10th. Returned to surgical department. Iodide of potassium, gr. i, t. i. d.

June 13th. Iodide of potassium, gr. x, t. i. d. Had

slight trouble in ear while on medical side. Complains much of pain, which is sometimes seated in the back of the head, sometimes in the ears, sometimes in the throat; worse at night and wakes her. Cheeks to-day are swollen, but not oedematous. Pupils widely dilated, equal. Can stand if supported, but sways; cannot walk. (Is now almost totally blind.) Knee-jerks increased and ankle-clonus on both sides.

June 20th. Memory good. Sings songs when asked. Tongue protruded straight. Great variability of pulse. Ataxia not well marked in upper extremities. Right lower extremity weaker than left. Cannot sit up in bed or stand without much support.

June 21st. For past week has wet bed occasionally; now complete incontinence for a day or two. Cannot perceive light.

June 25th. Record much as previous. Left eyelid droops a little more than right. There is now marked paresis of both upper extremities, but more right than left. Touches nose fairly well with right forefinger, less well with left. Right triceps reflex a little stronger than left. Considerable paresis right lower extremity, less of left lower extremity. Ankle-clonus right more marked than left.

June 27th. Operation by Dr. Bradford.

After the operation was decided upon, the usual steps were taken in preparing the patient, and in securing complete asepsis. The child's general condition was excellent, and appeared to justify an operation. After anesthesia (ether having been administered with a previous subcutaneous injection of morphia and atropia) the child was placed upon her belly, and the face turned slightly to the left. The incision usually recommended in cases of cerebellar tumor was made; namely, a curved incision with convexity upwards, extending from one mastoid process to the other, reaching upwards as far as the superior line. The flap was rapidly dissected downward; an attempt being made to remove not only the flap, but any of the pericranium that adhered to it. Not more than the usual amount of bleeding was met with, until the median line was neared, when a jet of blood was noticed issuing from one of the small foramina occasionally seen in the skull. This bleeding was checked by the insertion of a splinter of wood, cut from a match, which had been prepared for such emergency. A second jet from another foramen was also met, and the bleeding checked in the same way. As the flap was drawn from the median line, a slight amount of fibrous tissue was found to adhere to the skull, and bleeding was noticed to come from this region. The amount of bleeding was at first small, but afterwards became copious, and a third opening, of considerable size, was discovered. On examination the diameter of this opening was much larger than that of any foramen, and no match could control the bleeding. The finger was placed over this immediately, and a piece of cork inserted. The amount of bleeding which had taken place was considerable, though not more than is seen in an ordinary amputation, yet it seemed to cause great collapse, and in a few moments the patient was found to be dead. Artificial respiration was employed, but to no advantage. After death the trephine was applied directly over the opening, and the button of bone removed. On the inner surface the skull was found to be perfectly normal; but the opening, which could be distinctly seen, and which was smooth on the inside except in one spot was found to communicate directly with the sinus at

<sup>1</sup> Read before the Boston Society for Medical Improvement, February 9, 1891.

the junction of the lateral and median sinuses, the spot known as the torcular herophili. The dura was perfectly healthy, and there was no evidence of disease either in the dura or in the bone. The opening was enlarged by means of forceps, and on the right side at the projection of the posterior lobe of the cerebellum, a large, cheesy mass was easily recognizable. This was removed by the finger, and found to extend to a considerable depth forward and to the left, constituting evidently a tubercular mass.

The existence of this surgical anomaly could in no way have been foreseen. Its existence should serve as a surgical warning, that in operations of this sort, the pericranium should not be too fully stripped up in removing the skin flap in a region over the median line or over the occipital protuberance. How common such an anomaly as this may be, of course, there is no means of determining; as no such case has come to my notice, after investigating the subject with some care. I shall not attempt to define the nature of the opening, except that it was apparently a congenital one, and not due to the presence of disease. The operation could probably have been carried out to the end successfully, if this opening had been avoided. At least there was no reason to judge that there was any cause of death except the loss of blood.

Little need be said of the technique in operations on cerebellar tumors, as they differ in no way from what has been so carefully described in the details for the removal of cerebral tumors elsewhere. The question is simply one of the locality for insertion of the trephine, that is an anatomical one. The lines of indication for the place of trephining are clearly marked by natural limitations, namely, the foramen below, the median line on one side, the mastoid process on the other, and above, the superior line of the occiput, which marks the course of the lateral sinus.

The advisability of an operation on cerebellar tumor has been questioned, as until recently all cases were fatal. Messrs Maudsley and Fitzgerald of Australia, however, had reported a successful case; and Mr. Horsley writes me that he has recently met with another successful trephining for the relief of pressure, from a growth on the middle cerebellar peduncle. As diagnosis becomes more readily made, and cases present themselves for operation at an earlier stage, the results will in all probability be more favorable than those which have been as yet recorded. The present case illustrates a hitherto unforeseen danger, fortunately one which can, in future cases, be avoided.

No autopsy was permitted. The mass of the tumor removed through the opening, was three-quarters of an inch in depth, and from half to three-quarters in width. The material was hard and cheesy, and on microscopic examination by Prof. W. F. Whitney, there was found a narrow exterior zone of small round cells, with here and there a number grouped into minute rounded nodules; irregularly scattered about were large multi-nucleated bodies, giant cells, but the greater part of the specimen showed cheesy degeneration. No tubercle bacilli were found. The anatomical appearances were those found in large tubercles of the brain.

Prof. W. F. Whitney reports in regard to the bone as follows: The specimen is a circular piece of bone measuring 3.5 centimetres in diameter. The inner surface is marked by ridges of bone meeting at a central point similar in appearance to the point on the

occipital bone (named) the torcular Herophili. At this place is an irregularly oval opening, about 1.0 by .50 centimetres, passing obliquely through the bone

External and Internal Surfaces of Bone, from Photographs.

to open outside by an irregularly oval opening .75 by .50 centimetres, with a thin and slightly everted edge. The bone lying between these two openings has a worm-eaten look as if vascular sinuses had been found there. Into this space pass one or two large arterial foramina. When first seen the space was lined with a perfectly smooth tissue in which there was no evidence of any granulations or tubercles. It is probably a series of dilated blood sinuses with erosion of the bone.

#### TUMORS OF THE CEREBELLUM IN CHILDREN.

*General Remarks.*—The relative frequency of intracranial tumors in children is considerable, about fifteen per cent. out of all intracranial tumors, excluding specific, being found in children of ten years of age or under. Cerebellar tumors are relatively more frequent in children than in adults; that is, the percentage of tumors situated in the cerebellum to that of all intracranial tumors, is greater in children than in adults.

Out of 445 cases of intracranial tumors reported by Bernhardt in which the ages were given 68 (15 per cent.) were in children of ten or under. Steffen considers that the third year of life contains the largest proportion of children thus affected, and in the years following the number is diminished by one-half up to the age of ten. Out of a hundred cases of intracranial tumor collected by Mills and Lloyd, ten were under ten years of age, twelve between ten and twenty. Gowers says: "The first twenty years (of life) furnish one-third of the cases of cerebral tumor. The proportion in the first decade is 18.5 per cent. If tubercular growths be excluded, the proportion in the first twenty years of life falls to one-fifth." Hale White from one hundred autopsies of intracranial tumor at Guy's Hospital finds that more than half of those dying from cerebral tubercle were under ten years of age ( $\frac{2}{3}$ ).

*Relative Frequency.*—The relative frequency of cerebellum tumors as compared with all intracranial tumors in children is marked. Out of one hundred cases of intracranial tumors in children of ten years of age or under, taken at random, I find that in nearly fifty the cerebellum was affected. Some of these were cases of single tumors, in many the tumors were multiple. Starr, out of three hundred cases in persons under nineteen years of age, found ninety-six (thirty-two per cent.) cerebellar. Out of the one hundred cases of Mills and Lloyd of intracranial tumors at all ages only nine were cerebellar.

Bernhardt, out of four hundred and eighty-five intra-

cranial tumors at all ages, gives ninety cases (18.5 per cent.) of tumors of the cerebellum, but in addition to these there are a considerable number in which the cerebellum was affected although it was not the principal seat of the tumor.

**Forms of cerebellar tumor.**—The relative frequency of the various forms of cerebellar tumor in children has been referred to by various authors. Starr has found the following results from ninety-six cases of cerebellar tumor in persons under nineteen. We have obtained our results as seen in the table from one hundred and twenty-three cases in children of ten years of age or under.

As to the portion of the cerebellum affected in our cases: In thirty-two the tumors were situated wholly or largely in the right lobe, thirty-two were in the left lobe, and twenty in the middle lobe or centre. In seven cases both lobes were affected and in six the whole cerebellum. In seventeen cases there seems to have been more than one tumor in the cerebellum.

**Symptomatology.**—Tumors of the cerebellum may be wholly latent, although this is rare. They are usually accompanied by marked general, that is, non-localizing symptoms, headache, vomiting, vertigo and optic neuritis, followed by atrophy of the optic nerve, and frequently, also, mental depression, apathy and gradual mind-failure. There is almost invariably a considerable ventricular effusion, internal hydrocephalus, on the presence of which these symptoms largely depend. The hydrocephalus and the general symptoms above mentioned are apt to be specially marked in tumors of the cerebellum, because the position of the latter is frequently such as either to compress the vena Galeni or other efferent blood-vessels, or to diminish or occlude the communication between the ventricular cavities and the cerebro-spinal canal, in either case causing an excessive accumulation of fluid in the ventricles and the prominence of the symptoms thereby produced.

In addition to these general symptoms there also occur in cerebellar tumors certain others, which, while not so usual an accompaniment of intracranial irritation and compression, yet can hardly be considered as having any definite localizing value. Such, for example, is nystagmus. General clonic convulsions also sometimes occur, but are not especially common. Tremor on voluntary movement, resembling that of cerebro-spinal sclerosis is of doubtful localizing value.

Of more importance as a symptom of the position of the tumor is the presence of general tonic convulsions, opisthotonos and tetanoid contractions. When these occur to a marked extent and form a prominent feature, they have a certain localizing significance. Aside from these the true localizing symptoms of cerebellar tumors are few. They may be stated briefly as cerebellar ataxia, rotary movements, and the symptoms produced by the pressure of the tumor on the adjacent or neighboring parts, the pons Varolii, the medulla

oblongata and the adjacent nerve trunks. Cerebellar ataxia and rotary movements are the only symptoms due to the affection of the cerebellum itself.

Of the symptoms produced by pressure on other organs, the most important is the presence of paralysis due to pressure on the pyramidal tracts. We shall not, however, enter into the question of indirect or pressure symptoms.

Headache is, as we have said, a usual accompaniment of tumors in the cerebellum. It may be situated in the occipital region and in this case it may be of some slight value when taken with other symptoms as pointing to an affection below the tentorium. Frequently, however, it is situated elsewhere, for example in the supra-orbital region, hence its presence in another region than the occipital and its absence from that region does not contraindicate tumor in the cerebellum.

Vomiting, which occurs in many intracranial tumors and hence is classed as a general symptom, is said to be especially frequent in tumors in this vicinity and may be due in part to pressure on the medulla oblongata.

Double optic neuritis followed by double optic atrophy is an almost invariable symptom in any large tumor in this region. So long as this symptom were wanting, the diagnosis of cerebellar tumor would be a very uncertain one. This symptom is probably largely dependent on the hydrocephalus.

Vertigo, although occurring in many other intracranial affections and being frequently present in tumors in other portions of the cranial cavity, bears an especially prominent part in the case of cerebellar tumors. When considered in connection with the cerebellar ataxia and the rotary movements, of which, however, it is entirely independent, it seems possible that it may have a direct origin in the cerebellum itself, apart from any general cause. Of itself it is not a localizing symptom, but taken in connection with rotation and ataxia it would be of value as tending to confirm the diagnosis. In many young children its presence is naturally difficult to detect and it may easily be overlooked.

The mental conditions are probably, largely secondary to the hydrocephalus, either through compression or otherwise.

Of general tonic convulsions, opisthotonos and tetanoid spasms we can only say that they too, like vertigo, tend to confirm the diagnosis when other symptoms are present. They are supposed to be due in a general way to irritation of the medulla and should probably be classed among the indirect or pressure symptoms.

Cerebellar ataxia and rotary movements, with perhaps, certain forms of vertigo, are the only symptoms so far as we yet know, which are directly caused by irritation or destruction of the cerebellum. These, however, are distinctly characteristic and when they, or either of them exist, we have a definite localizing agent. It is not our purpose here to enter into the cause of these motions, so far as this is at present understood, but we can say that it is not a simple inco-ordination. Cerebellar ataxia is the term used to denote a peculiar reeling gait, resembling that of a drunken man and totally distinct from that so common in sclerosis of the posterior columns of the cord, the so-called locomotor ataxia. In cerebellar ataxia true inco-ordination of the muscles does not occur, at least in many cases. There is no loss of muscular sense. The upper extremities are frequently not affected (with

inco-ordination) even in the latest stages. The difficulty seems to be, not in the transmission of the central influences to the muscles, causing an imperfect and irregular passage thereof, but a direct affection of certain nervous centres, very possibly of a sensory character. In the so-called locomotor ataxia the difficulty seems due, largely, at least, to the irregular and imperfect transmission of motor influences, possibly in part to the affection of unconscious co-ordinating nerve centres in the cord. In cerebellar ataxia the dyskinæsis is due to impeded or imperfect action of the sense of equilibration. From affection of the sensory centres or other cause, the normal sense of equilibrium becomes perverted, abnormally increased or abnormally diminished in one or more directions, and this produces in the first place a sensation of general unsteadiness, often enhanced by the vertigo, which it probably also causes in part, and secondly, a sensation of leaning or falling in a special direction. This latter produces a tendency to compensate the supposed inclination or leaning and thus the patient is forced to bend or incline to the opposite side in order to feel himself in equilibrium. When the affection is severe the patient may fall to the side opposite to that on which he feels himself weak, that is, he may overbalance through mistaken sense of compensation. The direction of the fall, however, has only a doubtful significance, as there often seems a certain paresis on the affected side which causes the patient to fall on the side which seems to him weak. (By the affected side we mean the side of the lesion and the motor impairment connected with the ataxia is on this side.)

In severe cases or in those in which the loss of the balancing sense is very marked, there is sometimes found, in addition to simple want of balance and tendency to fall in a special direction, an impulse to rotation around a vertical axis. This seems to be due simply to an exaggerated loss of the sense of lateral equilibrium and the direction of rotation would appear to be from the affected to the sound side. This is present especially in cases where a lateral lobe or one of the middle peduncles is affected.

It was stated by Nothnagel and the view is still largely accepted, that the ataxic gait (cerebellar) exists only in those cases in which the middle lobe of the cerebellum is either directly or indirectly affected. It is certain, however, that the presence of this symptom does not necessarily imply any direct involvement of the middle lobe and in some cases it has existed to a very marked degree where such involvement did not occur.

The indirect symptoms due to irritation or pressure of the neighboring parts may be of essential aid in forming the diagnosis. We shall not discuss these symptoms here as they belong more properly in the consideration of functions of neighboring organs and are more or less self-evident. We will only note that the paralysis produced by pressure on the pyramidal tract is usually a late symptom, and that it is hemiplegic in form. It is generally permanent and is on the side of the body opposite to that of the lesion, thus differing from the cerebellar weakness which is on the same side as the lesion. We would also note a fact, which seems thus far largely to have escaped remark, and that is, the presence of temporary pareses of the extremities due to irritation of the pyramidal tracts. These were especially noticeable in our case.

Another symptom to which little attention has thus

far been drawn is the presence of a swelling of the face oedematous in appearance, but not pitting on pressure. (This has been especially noted lately in two cases which have come under our observation) and lasting a few hours to a few days. It is possibly due to some vaso-motor disturbance of the lymph vessels and is quite distinct from the flushings due to a similar disturbance of the superficial blood-vessels. This affects principally the cheeks and the middle portion of the face and the eyelids in our cases were not affected.

#### SURGICAL INDICATIONS; SURGERY OF THE CEREBELLUM.

The first question which arises is, What proportion of these tumors, if any, can be helped or cured by operation, and how far is operation in these cases justifiable? The latter question must be largely determined by the personal equation of the operator. I shall not enter into it at all, but shall only give the facts as far as they can be determined, and leave the conclusions to be drawn by each, according to his best judgment.

Hale White thought that out of one hundred autopsies of all intracranial tumors ten to fourteen were susceptible of operation. This means that, if as much had been known in regard to the tumor before death as could under the circumstances have been known, these cases were operable.

Starr, out of his three hundred cases of intracranial tumors in children thinks sixteen would have been successful if operated on. He also thinks that in cerebellar cases, one-third of the tumors can be reached by the surgeon.

These are general considerations. For the special problem of cerebellar tumors in children of ten years of age or under, we must consider special data. In the first place we have already stated the immense preponderance of tubercular disease, about seventy per cent. This being the case we have always to consider the probability that a given case is due to tubercular disease, unless there is special cause to suppose the contrary.

The three special conditions on which we determine the operability of any cerebellar tumor are its size, its exact position, and its nature (pathological formation). Dependent on these are several factors of much importance: (1) Its duration and the rapidity of its growth; (2) its vascularity; (3) its infiltration; (4) the involvement of neighboring structures, the medulla, etc.; (5) the probability of disease elsewhere, which would cause the removal of the tumor, even if successful to be of doubtful permanent benefit to the patient. Many of these elements cannot be determined. We will consider them separately.

*Size.*—The only method we have of in any way estimating the size of a cerebellar tumor, except in rare cases of growth through the bone, is from what we can judge of its nature and duration and from the pressure symptoms. Although tumors of the same nature grow with varying degrees of rapidity, if we can determine the nature, we can in some measure estimate its probable size in relation to the time of growth. As in most cases, however, the nature of the tumor is somewhat doubtful, we depend largely for our estimate of size on the pressure symptoms when they are such as to afford us any information. We do not include under this head the amount of hydrocephalus, as although this probably depends

largely on pressure on the venous channels and the communications between the general ventricular cavity and subarachnoid space, such pressure may be exerted by a comparatively small growth situated in a favorable locality, while a much larger one in another position would exert less influence. It is evident, however, that if there exist evidences of pressure in structures some distance apart and not supplied by the same blood-vessels, or otherwise so connected that pressure on the connecting links may affect them, the tumor must either be a large one or we have to deal with multiple tumors. The diagnosis between these conditions is often very difficult, owing to the frequency of multiple tumors in the cerebellum.

*Position.*—The exact position of the tumor can rarely be determined. This is due largely to the absence of localizing symptoms within the cerebellum itself. The only symptom referable to the cerebellum itself which can be of service in determining the position of the cerebellum affected is the direction in which the patient falls or rotates. The rotation is in many cases absent, but when present would seem to be of value. The direction in which the patient falls or towards which he inclines, when lateral, is of but doubtful value, as in some cases patients fall towards, and in others away from the side of the lesion; where the tendency is forwards or backwards this symptom may have more value.

The presence of reeling or staggering can hardly be considered to have much weight in the determination of the position of the tumor within the cerebellum, because although it is generally considered to be due to irritation or affection of the middle lobe, it is frequently found in tumors which do not involve the middle lobe directly at all; and Bramwell states that in his experience this symptom has been more unmarked in cases where the tumor has been confined to a lateral lobe. If the diagnosis of cerebellar tumor could be made without the presence of this symptom, its absence would suggest that the tumors were small and situated laterally.

More definite localization within the cerebellum may sometimes, however, be obtained by the effects of pressure on the neighboring organs, the pons, the medulla and the subjacent nerves. In many cases, however, localizing symptoms of this character, especially those due to pressure on the pyramidal tracts, only appear in the latter stages.

*Pathological Character.*—In regard to the pathological character of the tumor little can be determined from its direct symptoms. The general rule that fluctuations and rapid changes in the blood-pressure and general condition of the patient are more liable to occur in vascular than in non-vascular tumors, probably holds good here, but in these cases we are especially likely to find these changes affected and complicated by the conditions of the hydrocephalus, which is influenced by other factors than the vascularity of the tumor. Our principal means of determination, therefore, lie in the history of the case, the duration of the tumor, the apparent rapidity of its growth, the evidence of the presence of other tumors either intracranial or in other organs, or the presence of tubercular disease elsewhere. It goes without saying that, where tubercular disease exists elsewhere or where there is a strong family history of tuberculosis, the probabilities in favor of the tubercular nature of the tumor are much increased. In like manner the pres-

ence of sarcoma, carcinoma or of gumma elsewhere, would suggest the probability that the cerebellar tumor was likewise of this character.

Where no evidence is obtainable from the history or condition of the patient, we must still remember that the large percentage of tubercular tumors always causes a probability in favor of the tumor being of this nature. Multiplicity of intracranial tumors also points on the whole to their tubercular character; though many other tumors are also multiple, sarcomata and carcinomata, gummata. If a tumor be of extremely slow growth or appears to have become passive, we may suspect a growth from the dura or from the bone.

The rapidity of growth of a tumor affects its operability in two ways. In the first place, indirectly, as the operation to be performed must be performed as soon as possible in order to deal with as small a growth as we can. Secondly, as a means of diagnosis of the character of the tumor. On the whole sarcomata, carcinomata and gummata grow quickly, while tubercular tumors, gliomata, cysts and myxomata are slow. Sarcomata from the membranes and osteomata may be very slow.

The vascularity of a tumor affects its operability to a certain degree, and should when possible, be taken into consideration. In cerebellar tumors it seems to be often indeterminate. Pseudo-apoplectic symptoms and fluctuations in the blood-pressure point to it.

The question of infiltration can only be determined from the pathological character of the tumor. Except the long duration in some gliomata we have no intrinsic data.

The question of the multiplicity of tumors is very important. Where evidence of the presence of tumor in other parts of the body exists, or where tubercular or syphilitic disease manifests itself elsewhere, the case is simple. The same may be said where we have evidence of multiple intracranial tumors. In the latter case certainly one would hesitate long before considering any operation justifiable.

But the important question is, What are the chances in the case of any given cerebellar tumor in children of ten or under, that we have to deal with a simple tumor, and not with either multiple tumors or with dyscrasic manifestations such as tubercular meningitis, military tuberculosis, or in the case of gummata with syphilitic lesions of another character?

These questions can only be settled by statistics. We find out of 121 tumors that 48 (39.6 per cent.) are single and uncomplicated. (This number is probably too large as we have counted here all those in which no special mention of multiplication or complication was made.) Fifty-six (46.2 per cent.) were multiple, and in addition to these 17 (14 per cent.) showed disease, usually tuberculosis, elsewhere in the body. Out of 84 tubercular tumors we find 48 (57 per cent.) multiple and 17 (20 per cent.) complicated by tuberculosis or other trouble elsewhere, and only 19 (22.6 per cent.) reported single and uncomplicated. It must be remembered, however, in considering these figures that these results are all obtained at autopsies, and that it is very probable that in earlier stages many more of these cases were uncomplicated and single.

Of our gliomata, two were multiple; ten, including a glio-sarcoma, were single; no lesions elsewhere reported. Sarcomata, single, nine, including two

angio-sarcomata; and multiple, two, one melanotic. Carcinomata are probably always secondary. Gummata are frequently complicated or multiple.

Of surgical operations for tumors of the cerebellum, we can find but four up to the present date. Of these, three were fatal and one successful. These cases are:

(1) May. Male, seven. Tubercular tumor, right lobe of cerebellum. Death in a few hours, from shock. (*Lancet*, 1887, 1, 768.)

(2) Suckling. Female, twelve. Glioma, left lobe of cerebellum. Death in forty-eight hours, from shock. (*Lancet*, 1887, 11, 656.)

(3) Horsley. Male, eighteen. Tubercular tumor, chiefly in right lobe of cerebellum. Death in nineteen hours. (*British Medical Journal*, 1887, 1, 863.)

(4) Mandsley. Male, twenty-eight. Tumor pressing on left lobe of cerebellum. Not removed. Recovery from operation, and improvement. (*Transactions Intercolonial Medical Congress of Australasia*.)

### AN EPIDEMIC OF TYPHOID FEVER IN LOWELL, MASS.

ABSTRACT OF A REPORT UPON THE SANITARY CONDITION OF THE WATER-SUPPLY MADE TO THE LOWELL WATER BOARD, APRIL 19, 1891.

BY PROF. W. T. SEDGWICK,  
Massachusetts Institute of Technology, Biologist to the State Board of Health of Massachusetts.

(Continued from No. 17, page 402.)

#### TYPHOID FEVER EXCESSIVE IN LOWELL FOR MANY YEARS.

DRINKING-WATER from the Merrimack River has now been in general use in Lowell for many years, and therefore, before we can venture to charge the river with the responsibility of the recent epidemic of typhoid fever we must, in fairness, inquire if the city water has been above suspicion hitherto.

Here, fortunately, we may avail ourselves of a thorough statistical investigation made for the State Board of Health by Mr. Hiram F. Mills, Member of the Board and Chairman of the Committee on Water-supply and Sewerage. I quote (with slight changes) from an official letter recently addressed by Mr. Mills to the mayor of Lawrence:

"Typhoid fever is one of the preventable diseases, and in considering steps to be taken for its future prevention, the question of first importance is, Whether the cause of the prevailing sickness is temporary and exceptional, or continues from year to year?

"From the registration reports we find that for the twelve years, from 1878 to 1889, the yearly average number of deaths from typhoid fever in all of the places in the State which are now cities has been 4.62 deaths for each 10,000 inhabitants.

"The number of such deaths in each of the cities may be found in the following table [see next column].

"In this period of twelve years, Lawrence stands next to the highest with a yearly death-rate, from this cause, of 8.33 per 10,000, and Lowell follows next with 7.63.

"There are four cities larger than Lawrence, namely: Boston, Worcester, Cambridge and Lynn, whose yearly death-rate from typhoid fever averaged 3.91 per 10,000, or about one-half that of Lawrence and of Lowell, and the death-rate from this dis-

ease in Lawrence and Lowell was far above that of the average of the cities of the State.

AVERAGE NUMBER OF DEATHS IN THE CITIES OF MASSACHUSETTS BY TYPHOID FEVER.

Per Year, for Each 10,000 Inhabitants, for the Twelve Years 1878-89.

Holyoke . . . . .	8.93	Brockton . . . . .	4.01
Lawrence . . . . .	8.33	Lynn . . . . .	3.87
Lowell . . . . .	7.63	New Bedford . . . . .	3.80
Chicopee . . . . .	7.45	Newton . . . . .	3.65
Fall River . . . . .	6.32	Malden . . . . .	3.54
Springfield . . . . .	5.29	Worcester . . . . .	3.33
Taunton . . . . .	5.02	Newburyport . . . . .	3.25
Haverhill . . . . .	4.83	Cambridge . . . . .	3.23
Quincy . . . . .	4.68	Gloucester . . . . .	3.23
Pittsfield . . . . .	4.63	Fitchburg . . . . .	3.16
Marlborough . . . . .	4.39	Woburn . . . . .	2.95
Salem . . . . .	4.35	Schenerville . . . . .	2.55
Boston . . . . .	4.32	Chelsea . . . . .	2.59
Northampton . . . . .	4.04	Waltham . . . . .	2.42
All of the cities . . . . .		4.62	

"The deaths of the past year are not included, in order that we may see the relative position of Lawrence and Lowell in ordinary years.

"Turning again to the tables, to see if the condition of these cities is improving or deteriorating, we find the following average death-rates from typhoid fever, per 10,000 living for the four years, 1886 to 1889:

Lawrence . . . . .	10.30	Haverhill . . . . .	4.08
Lowell . . . . .	9.53	Boston . . . . .	4.05
Fall River . . . . .	6.40	Cambridge . . . . .	3.80
Holyoke . . . . .	6.13	Worcester . . . . .	3.11
Chicopee . . . . .	6.06	Lynn . . . . .	2.24

"The average for all the cities of Massachusetts in these four years was 4.59.

"Here we find Lawrence in these four years (next previous to and not including the last year) with the greatest death-rate from typhoid fever of any city in the State, amounting to 10.30 deaths yearly for each 10,000 inhabitants; followed closely by Lowell with 9.53; and then by Fall River with less than two-thirds as many.

"Lowell here has nearly three times, and Lawrence has more than three times as many deaths by this disease, for the same number of inhabitants, as the average of the four larger cities of Boston, Cambridge, Worcester and Lynn; and both have more than two times the average of all the cities of the State.

"It is to be noticed that the five cities having the highest death-rate from this disease are manufacturing cities, and there may be reason in attributing a part of the cause to the mode of life in such cities being poorly adapted to care in sickness; but on the other hand it may be seen by the Twenty-first Annual Report of the Board, page 395, that the mortality rates of Lawrence, since it became a city, compare favorably with the mortality rates of the city population of the State, taken as a whole; and Lowell is not essentially different, in this respect, from Lawrence.

"The diseases in which the death-rates of Lawrence and Lowell especially exceed those of other cities, are typhoid fever and diarrhical diseases, both of which are regarded as especially dependent upon the water used for drinking.

"Comparing these manufacturing cities we find there are twenty more deaths by typhoid fever, each year, in Lawrence than in the same number of inhabitants in Fall River; and in Lowell the condition is but little better than in Lawrence.

"These two cities, Lowell and Lawrence, both well situated, well regulated, and comparing favorably for general healthfulness with other cities in the State, have fifty per cent. more deaths by typhoid

fever, for the same population, than any other cities in the State.

"These are the only two cities in the State which draw their water for drinking from a river, into which, within twenty miles above, sewage is publicly discharged.

"Within nine miles above the Lawrence water-works are the Lowell sewers; and within nine miles of the Lowell water-works is the State line, with the city of Nashua five miles beyond. Sewage from towns in Massachusetts on the Nashua River, is freely turned into New Hampshire, and thence into the Merrimack River; and sewage from nearly one-half of the State of New Hampshire enters by the Merrimack River and flows through Massachusetts, past the cities of Lowell and Lawrence. Having no means of checking the entrance of the latter pollution was probably the controlling reason why the Commonwealth in 1878, by special statute, made this river a free receptacle for sewage.

"The amount of sewage that has directly entered the river and its branches during the chemical examinations of the past three years is estimated to be about one gallon in six hundred gallons of the river water passing Lawrence (or about one-half of this quantity at Lowell), and there has been no more impurity in the water that could be detected by chemical analysis than in about one-half of the drinking-water supplies of the State obtained from ponds and streams; but the facts which have been presented, showing that these two cities have so much higher death-rates from typhoid fever than any other cities of the State, together with what is known of the relation of typhoid fever to sewage-polluted drinking water, are the strongest grounds for concluding that even with the small amount of organic impurity in the water, as shown by chemical analysis, the disease germs of this disease are able to pass, and do pass, from one city to the other in the water of this river, and from the cities above Lowell to Lowell.

"More than one-half of the cities of the State had public water-supplies introduced within the years from 1869 to 1877. In the table below are given the number of deaths from typhoid fever yearly in 10,000 inhabitants in each of the cities introducing water in the above period for the ten years previous to the period, and for the twelve years following it:

CITIES.	Yearly deaths by typhoid fever per 10,000 people, 1869-1878.	Date of introduction of water-supply.	Yearly deaths by typhoid fever per 10,000 people, 1878-79.	Percentage better or of the former.
Holyoke . . . . .	6.73	1873	8.93	133
Lawrence . . . . .	8.51	1875	8.33	100
Lowell . . . . .	8.46	1872	7.63	124
Fall River . . . . .	7.78	1874	6.32	81
Springfield . . . . .	9.67	1875	5.29	55
Taunton . . . . .	6.12	1876	5.02	82
Northampton . . . . .	10.28	1871	4.94	48
Lynn . . . . .	9.06	1871	3.87	43
New Bedford . . . . .	7.77	1869	3.80	49
Newton . . . . .	6.67	1876	3.65	56
Malden . . . . .	8.94	1870	2.54	28
Fitchburg . . . . .	10.59	1872	3.16	30
Woburn . . . . .	8.29	1873	2.95	36
Somerville . . . . .	4.28	1867	2.65	62
Chelsea . . . . .	5.97	1867	2.89	48
Waltham . . . . .	8.32	1873	2.12	26

"Of these sixteen cities, all but three had less typhoid fever after introducing public water-supplies than before; and their average number of deaths from this cause was less than one-half of the number of deaths when they used water from wells.

"The three exceptional cities are Holyoke, Lawrence and Lowell, whose death-rate from typhoid fever in the above period, since the introduction of water has not been less than previously.

"Holyoke, though receiving water from an outside source for general use, has used, to some extent in the mills, water from the canals filtered through gravel beds in the bottom of the canal or through some of the rapid filters used by paper-mills. No investigations have yet been made to learn whether the people using the canal water in this way are more afflicted with typhoid fever than others; and it is a fact that during the past five years, since the canal water has been more carefully filtered than formerly, the death-rate in Holyoke from this disease, though still high, is lower than in previous years.

"The continued high death-rate from this disease of Lawrence and Lowell which, as before stated, has, in the four years previous to the last, put them far beyond all of the other cities of the State, must, in large measure, in the light of the experience of the other cities, be attributed to the polluted water-supply. And the experience of the others gives promise that, with a pure water-supply, the death-rate by this disease may be reduced by one-half." [H. F. Mills, C. E., Official Letter to the Mayor of Lawrence, Mass., January 30, 1891.]

It only remains to add that I concur with Mr. Mills in attributing the excessive typhoid fever of Lowell and Lawrence to the use for drinking purposes of the polluted and infected water of the Merrimack River.

#### PROBABLE SOURCE OF THE EPIDEMIC OF 1890.

I have now shown that there was in Lowell in 1890-91 a severe epidemic of typhoid fever, and that this epidemic was not principally due to infected well water, or to infected canal water, or to infected milk. On the other hand, I have shown that the Merrimack River is seriously polluted, and that there is reason to believe that the typhoid fever which has been excessive in Lowell for years has come, chiefly, from the city water. It still remains to inquire if the epidemic of 1890 can be traced to any unusual infection of the Merrimack River. Having thus narrowed the inquiry, I shall now prove that the river was especially infected with typhoid fever excreta in August, September and October, 1890, at such a time and in such a place, as to offer a satisfactory explanation of the epidemic. I shall then show that the epidemic is not attributable to climatic conditions, or to local conditions, or to any other known cause and, finally, that all the phenomena of the epidemic, as well as the constant and long standing excess of typhoid fever in Lowell, are attributable to the use for drinking purposes of the infected water of the Merrimack River.

Typhoid fever, as has been shown above, was not much more abundant than usual in Lowell, during 1890, until September, when the epidemic began and ran the course already described. If we seek for the cause of this increase we shall look in vain to the canal water, to the well water, and to the milk-supply; but if we turn to the city water, we shall find that, while there does not appear to have been any special increase, but rather

a decrease of typhoid fever in the cities polluting the Merrimack River above Lowell, as compared with the previous year, there was, nevertheless, a small epidemic of typhoid fever upon a feeder of the Merrimack less than three miles above the intake of the Lowell Water Works.

In the village of North Chelmsford, Mass., which is almost a suburb of Lowell, there appeared, on July 27, 1890, a case of illness which, although apparently not well defined, must, I think, in view of the phenomena which succeeded it, be regarded as a mild case of typhoid fever. The patient had been working in a worsted mill at North Chelmsford, which employs many hands, and drains almost directly into Stony Brook, a small stream emptying into the Merrimack at a point just above the North Chelmsford railroad station, about two and one-half miles above the intake of the Lowell Water Works, but on the opposite side of the river. The patient is positive, however, that she had no diarrhoea while at work in the mill, and as the case is at best a doubtful one, it need not be further considered.

On October 30th, Dr. Edwards was called to a severe case of typhoid fever, namely, that of a young man who had been working regularly until, and including, October 27th, in the North Chelmsford Iron Foundry. While there, and especially on October 25th and 27th, this patient, whom we may designate as Stony Brook Case No. IV, used the foundry privy which directly overhangs Stony Brook (see photograph). On the days just mentioned, although the patient was extremely ill and ought not to have tried to work, he did so, nevertheless, but was affected by a diarrhoea so severe that he was compelled to resort repeatedly to the privy and necessarily spent most of his time there. This patient soon after died.

Nearly a month before this time a brother of Case No. IV, a workman at the ice-houses of the Boston Ice Company at North Chelmsford, fell ill, and appears to have had a mild case of typhoid fever. He consulted a physician in Lowell, and reports that the physician pronounced the case to be typhoid fever; but, as he made but one office visit, and consulted no other phy-

On August 21st, Dr. Edwards, of North Chelmsford, was called to visit a case of illness which proved to be well-defined typhoid fever. This patient, fourteen years of age, had also been working in the worsted mill, but I am told that she had no diarrhoea while there, although she had other well-marked prodromal symptoms. We may designate this case as Stony Brook Case No. I. Case No. I, worked in the mill regularly until August 23d, inclusive, when she went home, and was ill for weeks with typhoid fever. There was probably no contamination of the brook, however, during the home illness of this or of any other of the Stony Brook patients. Their contamination of Stony Brook and, therefore, of the river ceased, in every case, as soon as the patient was obliged to stay at home.

Another patient, sixteen years old, who had been working regularly in the worsted mill until September 6th, became, I am told, ill. She was first seen by Dr. Edwards on September 9th, and the case proved to be well-defined typhoid fever. This patient we may designate as Stony Brook Case No. II.

The diagnosis must be considered incomplete. I am satisfied, however, that this patient, whom we may designate as Case No. III, had a mild case of typhoid fever, and his mother and one sister and two brothers, with whom he lived, appear also to have had typhoid fever. With the exception of one brother (Case No. IV), none of the others had contaminated the brook.

Case No. III used often, just before his illness, a privy near the ice-houses, overhanging Stony Brook. The exact time of his illness I have not been able to ascertain, but it is certain that his prodromal period, during which the privy was used, was somewhere between September 23d, and October 9th.

The epidemic at North Chelmsford, if such it may be called, was confined to three families, and affected, in all, eight cases, one of these being fatal, but only four appear to have infected the river. The points of infection of the brook by Cases No. III and No. IV have already been indicated, and are shown by photographs. The tail-race through which all the sewage of the worsted mill enters Stony Brook is also shown

by a photograph. This, therefore, is the point of infection by Cases No. I and No. II. . . .

If, now, we plot the dates of probable infection of the river by these cases, allowing two weeks in each case to cover the period before they quit work and took to bed, we shall find that they appear to bear a direct and unmistakable relation to the epidemic in Lowell. The severest case is No. IV, namely, the one in which we have the most direct and positive evidence of repeated and extensive infection of the brook from an overhanging privy.

We have concluded above from the intrinsic evidence of the epidemic itself, that the infection underlying it must largely have fallen upon the city as a sudden blow somewhere within the last two weeks of October. I believe that the principal blow was dealt by Case No. IV, who, as we have seen, infected the Merrimack River, at North Chelmsford, within the two weeks previous to October 27, 1890.

It will naturally be asked how long a time would be required for the transportation of fecal matters bearing the infection from the foundry privy in North Chelmsford to the intake, the reservoirs and the city service of Lowell? Or, in other words, for the passage of typhoid fever bacilli from one human intestine in North Chelmsford to another in Lowell? Here I am unable to give precise data, but I have reason to believe that twenty-four hours would often be ample. Concerning the possibility of the passage of such matters from one side of the river to the other, it must be kept in mind that the Merrimack at this point is a pond rather than a stream; at times the current is even reverse, and a thorough mixing must often speedily ensue. Of the precise conditions which existed in the river in the latter part of October, I have no knowledge, but it is a fact which cannot be overlooked, that within a month from the time of infection by Case No. IV, an epidemic of typhoid fever in Lowell rose very rapidly, culminated and began to decline. Within the same month there was also the greatest mortality of any month during the epidemic, namely, thirty deaths from typhoid fever. The earlier phases of the epidemic are readily explained by the earlier cases at North Chelmsford; the later phases, by the persistence of the infection in the reservoir or in the pipes, and especially by secondary infection, from person to person. The sluggish decline observed upon the diagram of monthly mortality and upon the other diagrams, is probably due to the fresh secondary cases which are always a feature in epidemics of typhoid fever. The periodic fluctuations in the curve of weekly morbidity are probably due to fresh reinforcements of the same kind. In support of this view it will be observed that they occur at intervals of the incubation period of typhoid fever, namely, every two weeks, — a fresh crop of cases appearing every fortnight.

From prolonged personal investigation of the detailed history of the Stony Brook cases and from their apparently unmistakable relations to the epidemic, which are shown upon the diagrams, and in the total absence of any other known cause, I am convinced that the infection of Stony Brook by these cases was the principal cause of the epidemic of typhoid fever in Lowell, and indirectly of that in Lawrence, in 1890-91.<sup>1</sup>

<sup>1</sup> Dr. Edwards informs me that there has been no similar epidemic in North Chelmsford for forty years.

In the present state of our knowledge of the etiology of typhoid fever, it is not reasonable to suppose that geographical position or climatic conditions are real sources of this disease. The following table shows conclusively that Lowell and Lawrence, alone, of all the cities in the Merrimack Valley, suffered to any unusual extent, from typhoid fever in 1890. It appears, however, that in 1889, with no special epidemic, typhoid fever was excessive, or endemic, in Lowell and Lawrence.

#### TYPHOID FEVER IN THE MERRIMACK VALLEY.

Deaths per 100,000 of inhabitants, census of 1890.

					34.0	32.0

NOTE.—The figures for Lawrence in 1890 are not much higher than in 1889, because the epidemic did not become marked in Lawrence until December, that is, much later than in Lowell.

This table abundantly proves that the cause of the recent epidemic was not general or climatic, and the fact that Lowell and Lawrence both suffered, although only in respect to typhoid fever, excludes purely local influences. I have not been able to discover any explanation whatsoever, of any kind, that accounts in any degree for the recent epidemic, except the fact to which we ought most naturally to turn, namely, the undoubted infection of the Merrimack River. I believe that this explanation accounts completely and satisfactorily for the Lowell and Lawrence epidemics as well as for the constant excess of typhoid fever from which these cities have long suffered. I think that we have good reason to believe that the germs of typhoid fever have been carried alive and virulent three miles, namely, from Stony Brook to Lowell. The history of the Lawrence epidemic of 1890-91 indicates that they can also be carried nine miles, namely, from Lowell to Lawrence, and there is good reason to believe that, under favorable conditions, they may be transported from Man-

chester, N. H., or even from more distant points, arriving at Lowell alive and virulent.

#### SUMMARY.

In view of all the foregoing facts I find myself compelled to report to your Honorable Board my firm conviction, that there is danger, both constant and grave, in the water of the Merrimack River at Lowell.

### SIMULATED PRIMARY DEMENTIA. A MEDICO-LEGAL CASE.<sup>1</sup>

BY ARTHUR H. NICHOLS, M.D.

From the time when Ulysses feigned insanity to escape the hardships of the Trojan war, the simulation of dementia has been one of the most common forms of malingering among soldiers disposed to shirk military service; while the records of all prisons likewise contain frequent fictitious examples of this malady, the subjects of which, when transferred from jail to hospital, are very likely to make a speedy escape from confinement.

The ludicrous instance of rascality here reported, is remarkable from the youth of the delinquent, and the circumstance that the disorder having been induced, as was alleged, suddenly, as the result of external violence, was made the basis of a claim for heavy damages in an action of tort, and this claim was supported by physicians in good standing. The case was tried in the month of October, 1890, in the Superior Court, where the claimant was produced in public from day to day, and even placed upon the witness-stand.

The plaintiff, an ignorant, vulgar lad, fifteen years old, of mixed French and Italian parentage, and without inherited taint, had been employed as assistant upon a covered milk-wagon, which ran regularly at an early hour each morning from Arlington to Boston. On the first of January, 1890, as this wagon was on its route before sunrise, it was run into from behind by an electric car moving rapidly, overturned and partly demolished, pitching the lad backward from the seat into the body of the wagon amongst the milk-cans, and producing, as was stated, contusions and sprains about the head, neck and back, though on this point the evidence was conflicting. At first he showed no sign of serious injury, but talked freely and rationally and assisted in leading off the horse and collecting the articles scattered from the team. When he reached home, however, a very marked change was observed in his deportment. He now began to complain of pain in head and neck, and there soon supervened a state of stupor, after which no intelligent response to any questions could be elicited. An irregular practitioner who was called in at this time, thought he found a lump on the back of the head, superficial bruises of the back and tenderness over the middle cervical vertebra, though the family physician, who saw the boy a few days later, could detect no outward marks whatever of injury. This condition of mental stupor or vacuity persisted, and the lad took to his bed, where he was said to have remained the greater portion of each day for over three months. At the end of this time his physical condition had materially improved, but it was claimed that the mental disorder had be-

come permanent, resulting in an almost entire loss of intelligence with occasional periods of partial unconsciousness.

The malady was seriously designated by the experts testifying in behalf of the plaintiff, as a pronounced, typical case of acute primary dementia offering no reasonable hope of recovery or amelioration, and this opinion was reiterated in the most positive manner and without modification. It was affirmed that the lad was a "mental wreck," an "imbecile," that he was unable to properly dress or undress or feed himself, or to move about without attendance; that he had been unable to do any labor since the accident except in imitation of others; that he could not give his own name in full nor his age; that he was unable to answer simple questions, or, if he replied at all, his answers were generally monosyllabic and irresponsive; that he had been entirely unable to do anything for himself; that apparently he had no recollection of the accident nor of any events in his life before or since then; that he has been unable to recognize his nearest relatives and friends; that he was found not long after the accident pulling hot ashes out of the stove upon his bare legs; that he had tried to set the house on fire, and had cut up a harness, and in other ways manifested a destructive tendency; that when sent to get any article he would fetch something different.

When led to the witness-stand the lad showed no peculiarity of gait. He maintained a fixed stupid expression; did not rest his eyes upon the ground; appeared free from embarrassment or nervousness and did not look woe-begone or dejected. To the question of his counsel, "What is your name?" he answered "George," and when asked, "Did you get hurt?" he replied "No." To other simple questions he attempted no response, but maintained the same stolid look of indifference and imbecility as if lost in vacancy, which for the time being drew successfully upon the sympathies of the spectators and jury. Interrogation by the defendant's counsel was of course unnecessary and impracticable, and when the lad was ordered to take his seat, he paid no attention and was therefore led from the stand. Upon one occasion only in the court-room was this mask-like vacaney or imbecility of countenance dropped. A jocose retort from an astute country witness provoked a general laugh in which the claimant inadvertently joined; but apparently appreciating the significance of this involuntary display of intelligence, his laugh was promptly cut short, and the former condition of facial atony resumed.

As an illustration of the incompetent and discreditable medical evidence now admitted to our courts of justice, it may be mentioned that the most important medical witness for the plaintiff in this case testified to having received his degree from a notorious eclectic institution in Philadelphia (since happily suppressed) after a course of study lasting two months. He claimed, indeed, to have previously attended lectures at the Harvard Medical School, but admitted that his attendance there was informal and occasional, and at a time when he was performing the duties of nurse in the vicinity; that he had never paid for any courses and had not been inscribed as a student in the school. The subsequent cross-examination of this gentleman by an experienced lawyer well-informed as to the medical features of the case, revealed a degree of ignorance

<sup>1</sup> Read before the Boston Society for Medical Observation, March 2, 1891.

almost beyond credence, and provoked indignant condemnation from even the plaintiff's counsel.

My first examination of the claimant in behalf of the defendant corporation was made at the house of his employer with whom he boarded, and in presence of his counsel and physicians, about seven weeks after the accident. He lay in bed with eyes nearly closed and appeared semi-unconscious like one in a delirium. At times he uttered a few incoherent or disconnected words but no intelligent reply to any questions. Externally he appeared in perfect physical health, the body and limbs being symmetrical and well-developed, the muscles not flabby but uniformly firm to the touch, the skin of good color and neither moist or clammy, nor unduly dry. The circulation was natural, appetite and digestion unimpaired; sleep undisturbed; no derangement of the organs of special sense and no sensory symptoms; there had been no loss in weight. Great sensibility of the cervical vertebrae was affected, and whenever this part was touched in the course of the examination, he would strike out viciously with one or both arms; but when I leaned over his body in such a manner that if he lit out as usual he could not avoid striking me, his fists avoided my head and I was thus convinced that these muscular movements were all directed by an intelligent brain and with accurate calculation. By manipulating his neck at a moment when his attention was successfully diverted, it was satisfactorily demonstrated that the painfulness located at this point was purely fictitious. When ether was administered he resisted vigorously, and his head and neck were moved about with a degree of freedom hardly consistent with its previous sensitiveness. I had hoped that in coming out of the ether, more precise evidence of his mental condition might be shown by the remarks he would then make, but he retained sufficient sagacity at this time to remain taciturn. So far as could be learned there had been no signs of epilepsy, no delusions or incoordinations of muscular movements, nor had he displayed filthy or dirty habits. No choreic movements.

The conclusion drawn from this examination was, that the lad was a consummate rascal in the enjoyment of his usual mental and physical health, and that the morbid symptoms were all consciously, designedly and fraudulently simulated for the purpose of extorting money from the corporation; and this view was confirmed by subsequent developments. The difficult problem was now presented of how to procure evidence apart from medical testimony of such a nature as would appeal to the common sense of a jury, and thus establish, beyond reasonable doubt, the fraudulence of the claim. It is evident that the malingery of insanity can, as a rule, be successfully exposed only when circumstances admit of long-continued observation; for the simulators have only to adopt the rôle of obstinate silence or complete passiveness, in order to put an effectual stopper upon any attempt to analyze the state of the mind. It is at odd moments, therefore, when the delinquents are thrown temporarily off guard, or when they fancy that they are not watched for the time being, that they are likely to betray themselves by actions inconsistent with the correct representation of the special malady which they are trying to simulate. In the present instance it was decided to completely ignore the claimant for a period of four or five months, upon the theory that any systematic attempt to keep him under observation would not only be

futile, but would furnish a continuous incentive toward persistence in the fraud: whereas left entirely to himself the prolonged acting without the encouragement of an audience would inevitably become irksome and difficult, especially when the heat of midsummer should become so great as to render in-door confinement and abstinence from all out-door sports a positive punishment.

Subsequent events demonstrated the wisdom of this course; for though the lad was kept closely confined to his room during the spring and early summer and access to him denied to all callers, the heat combined with enforced idleness became at length intolerable, and on the 18th of August, he was taken in a covered carriage to a farm-house in Bedford. Here, where he was presumably unknown, he remained until October 4th. Although efforts were made after his departure to conceal his whereabouts, he was traced by agents of the corporation, and was thereafter kept under rigorous surveillance with results most confirmatory of the theory of simulation, and supplying in cumulative form the precise evidence desired. It transpired that this change of environment to the salubrious air of central Massachusetts and the society of strangers was followed by a very sudden emergence from the state of mental and bodily torpor; for according to the testimony of upwards of twenty intelligent witnesses from this locality, the lad appeared perfectly sane and natural during the entire period of his sojourn there. It was proved by these people that he performed a variety of acts such as helping to saw, load and unload logs; driving teams on the highway and for ploughing, holding the plough; doing errands, helping to harness horses, riding horseback, cutting corn, painting a house, helping to move and tread down ensilage in a silo, driving a team for a man peddling vegetables and making two sales and receiving the pay therefor, frequently walking alone on the highway and moving about freely without attendance, dressing and undressing and feeding himself, walking alone to Clinton, three miles distant, to get his shoes mended and in the afternoon of the same day riding thither on horseback for them, conversing frequently and intelligently with many persons on different occasions, engaging in play and sports with other boys; receiving, when employed by different farmers, the ordinary rate of wages and doing his work satisfactorily, exhibiting all the while nothing unusual in his appearance or conduct.

This unimpeachable evidence of recent intellectual activity proved of special service in determining the opinion of the experts who testified in behalf of the defendant corporation; for the symptoms observed during the examination granted in the course of the trial were mostly of negative character and in many respects unsatisfactory and inconclusive.

It was not to be denied that intermittent periods of sanity may occur in the course of acute dementia, especially in the young; but the striking coincidence of this lucid interval with the sojourn in Bedford was not to be explained on this theory. Indeed this temporary restoration to health was not disclosed or even admitted by the plaintiff.

It may be stated as a general rule, that where in the presence of conflicting evidence a certain degree of doubt is raised as to the reality or significance of symptoms, the average jurymen inclines to give the benefit of this doubt to individuals rather than to a corporation. But he is also sensitive to the imputation of gullibility,

and thus statements which involve a draft on his credulity serve to render him keen in sifting and weighing the remaining evidence and more ready to discredit and reject evidence as to symptoms or occurrences intrinsically improbable.

The question was asked, whether it would not be almost impossible for an inexperienced lad unfamiliar with the manifestations of dementia to so successfully simulate this complicated disorder as to deceive even physicians. The obvious reply is, that to conceive and represent for months all the characteristic phenomena of any one variety of insanity would indeed demand experience, intelligence and strength of will. But, on the other hand, the feigning of a few isolated and purely subjective symptoms is quite simple, requiring neither talent nor skill; being an artifice resorted to either for self-protection or to facilitate an attack, by birds, animals and insects. In the present instance there was a striking want of cohesion of the manifestations with the form of disorder which it was intended to imitate. The part was played in an ignorant and bungling manner by one poorly coached, and the intellectual absurdities and the grotesque extravagances would not have deceived any alienist, had a sufficient opportunity for subjecting them to the ordinary tests been afforded.

It was maintained that the lad's intellectual faculties had become obliterated, not by slow gradations but all at once, as if by some overpowering shock to the nervous system; but there was no adequate evidence to show that any such profound shock had been sustained. The brief attacks of semi-unconsciousness were not in harmony with this theory of dementia and were clearly feigned. The attempt to show the existence of pyromania was another suspicious circumstance; for the evidence on this point was of a flimsy character and referred to a single insignificant act, and the same is true with regard to the alleged tendency to destructiveness. Such acts, if real, might form a vent for the vehemence of acute mania, and are doubtless committed under the influence of delusions; but this patient had always manifested the minimum, not an excess, of cerebral action; and, as before stated, there existed no suspicion of any delusions. Among the minor points, the callousness of his hands was held as confirmatory of the statements as to continuous hard work recently performed.

The jury upon retiring were unanimous in the belief that the insanity was feigned; but in deference to the feelings of some who thought that possibly a local injury might nevertheless have been received, agreed upon the nominal award of \$500, although the judge in his charge had instructed, that if they should find any of the plaintiff's allegations to be fraudulent, as a matter of law they would be justified in discrediting all his statements.

The case here reported is not presented on account of its being unique or even rare; but rather as a sample of a number of bogus claims recently brought against individuals and corporations, and which, though from a medical standpoint quite as preposterous, have not always been as successfully defended. It is, therefore, to be regretted that in the present instance the exposure of fraud was not followed up by a criminal prosecution of the guilty parties, which might have resulted in the committal of the claimant and some of his abettors and instigators for conspiracy, deception and perjury.

## COUNTER-IRRITATION.

BY CHAUNCEY REA BURR, M.D., BOSTON.

THE following article is an attempt to systematize some of the material scattered about in medical literature on this subject, and in the daily experience of most of us, and while claiming no originality, save in the general arrangement of associated facts, may be of service in pointing out when and where this procedure should be employed.

Counter-irritation, as its name implies, is irritation exerted against existing irritation. It has an object, and this is, the diminution or abolition of all irritation.

Irritation, pure and simple, has also a remedial application, but its office is to stimulate, not to abolish metabolic activity, and it is therefore aside from the subject in hand.

Counter-irritation as such, has a limited application in this, that it is only in acute and subacute forms of disease that any amount of irritation exists, metabolic activity being the measure thereof.

Irritation of any sort, sooner or later, involves nervous agency, and counter-irritation, sooner or later, must operate through the same channels.

Finally, the evidences of nervous irritation being manifested in either the interior or exterior of our bodies, counter-irritation, to operate through the same channels, must be applied to either the interior or exterior of our bodies. It has, therefore, a medicinal as well as a surgical side.

With this introduction, I proceed to a discussion of the *rationale* of the system and shall then endeavor to apply it to a few examples.

And first, what occurs when a nerve is irritated? The only answer to this is, some form of metabolic activity, that is to say, muscular contraction or glandular secretion. The precise manner in which this is accomplished seems to be still a matter of doubt. But the *vis a tergo*, the nerve force itself, is gradually coming to be better understood. Instead of belonging to that class of phenomena associated with the release of potential energy, that is to say, chemical action, nerve force appears to be simply another name for kinetic or vibratory energy exhibited in nervous structures. In a gaseous medium, this same force is called, heat or light, or sound; in a liquid or solid medium, conduction, convection, electricity. The motive power is an actual mechanical force and this is, energy in motion. The method of propagation, is, in all instances, the same, namely, by bound and rebound among the particles themselves composing the conducting medium, or by compression and expansion, the whole process being summed up in the one word, *vibration*.

Two facts may be adduced in confirmation of this position: (1) the absence of satisfactory evidence to show that heat, itself the measure of metabolic change, is produced by the activity of a nerve, and (2) the failure of two experimenters, Wiedenski and Bowditch, to induce exhaustion in a healthy nerve by electric stimulation, the one after six hours continuous effort, the other after four hours.

If these results are confirmed by further experiment, as I firmly believe they will be, a very great light is thrown on the whole subject of nervous activity, and the laws determined for heat and light and sound, will also apply to the transmission of nervous energy.

There is only one of these laws which I wish to

apply to-night to the subject in hand, and that is the establishment of nodes in a conducting medium.

A nerve, considered mechanically, is to all intents and purposes, a rod fixed at one end and free to move at the other. Vibrations therein are in the main longitudinal. Now, if two counter-waves are travelling in opposite directions in this rod, it is evident that they will meet somewhere, and a nodal or "dead" point be established. This nodal point will be brought to rest by the counteracting forces on either side, and the original waves reflected. The rod, in fact, is split up into two rods, and each of these vibrates in twice the time that the original rod vibrates. Furthermore, it is impossible, by the laws of physics, to disturb the relationship existing between the mass to be moved, the force necessary to do this and the time in which it is accomplished, without, at the same time, altering one or more of their relative values. If the rate is increased the force is diminished and hence the effects dependent on this force are diminished. In the case of a nerve, this simply means, that the evidences of metabolic activity are diminished. Therefore, if a wave of nervous energy, caused, it may be, by reflex peripheral irritation, is travelling down a nerve, at the same time that a counter-wave of nervous energy, caused, it may be, by direct peripheral counter-irritation is travelling up the nerve, a node will be established, and the force of each wave diminished one-half. Hence the metabolic activity will be diminished one-half. It is a simple mathematical problem to calculate what will be the result if each of these reflected waves is met by counter-waves. The force of each will be still farther diminished, and the evidences of the original irritation greatly diminished, if not indeed, abolished.

A requisite to success in the use of counter-irritation is that it should be continued for some time, for morbid impressions are only rarely transitory. Dr. J. Mortimer Granville, in the *British Medical Journal* for 1882 (Vol. 1, p. 339), has given the results of his efforts in this line, by the use of an automatic percussor. He writes *apropos* of what has already been said:

"Acute or sharp pain, is, I believe, like a high note in music, produced by rapid vibrations, while a dull, heavy or aching pain resembles a low note or tone, and is caused by comparatively slow vibrations. A slow rate of mechanical vibrations will, therefore, interrupt the rapid nerve vibrations of acute pain, while quick mechanical vibrations more readily arrest the slower. The aim, if I am right in my conjecture, should be to set up a new set of vibrations, which shall interrupt or change the morbid set by introducing discord."

So much for the exposition; now for a few examples.

Counter-irritants are generally divided into three classes, according to their degree of action, to wit: (1) Rubefacients, (2) Vesicants, (3) Pustulants. Examples of the first class are found in heat, including the actual cautery, galvanism and the static spark, dry cups, mustard, iodine, turpentine. Of the second class may be mentioned, Spanish fly, and the confined vapor of ammonia and chloroform. Of the third class, croton oil, tarrated antimony, caustic potash, strong solutions of nitrate of silver, issues and setons. Of course, there are many others, but these will serve for the purposes of illustration.

Now all of these irritants are applied externally, they are, therefore, in a measure, surgical. They are all, moreover, applied over the seat of pain, although

their action is by no means limited to the place of application. Continuity of action is secured by continuity of irritation. We can therefore apply a rubefacient frequently, or a vesicant or pustulant less frequently.

Suppose a knee-joint to develop the classic signs of inflammation, heat, redness, swelling, pain; and suppose the cause to have been removed, that is, it may have been a case of trauma, we observe that the muscles moving the joint are more or less rigid and resist passive motion. That is what would be expected from the nervous distribution to the parts. For if we consider what nerves control the muscles, for example, flexing the joint, we are struck with the fact that the same nerve (the great sciatic) through its branches, supplies a part of the joint itself and a part of the integument over it. The same holds true for the remainder of the nervous supply here, and for all the joints of the body, namely, that the muscles moving a joint and the integument over it, are supplied by the same nerve or nerves which feed the joint itself. This being so, it follows, that the same irritation which paralyzed the vaso-motors of the synovial membrane is transmitted to the central nervous system, there reflected and is felt at the periphery as pain, and manifested as spasm.

Each nerve fibre is insulated from its fellows in the nerve sheath, but there is a point somewhere, either in the central gray-matter of the cord, or in the sympathetic ganglia, where the axis cylinders of all nerves merge. Wave vibrations can thus be sent from one nerve into another, or as we say "reflected." If then, counter-irritation is applied over the seat of pain, a wave of energy is sent up the sensory nerve at that point, and somewhere, either in its direct or reflected path, meets the original wave from the inflamed joint and there establishes a node. Each wave is thus reflected back to its starting point, but it arrives there with its force diminished one-half, and its capability of doing mischief diminished one-half. The strain on the vaso-motors has been lessened; they commence again to act; the blood-vessels contract, the serum is reabsorbed, the muscles relax and the joint is convalescent.

It is not to be supposed that one application of a counter-irritant will do all this, nor perhaps a dozen applications, but so long as pain, or spasm, or both, exist, so long will counter-irritation be found advantageous.

Another familiar example of external counter-irritation is seen in pleuritis. Here the nervous supply is furnished by the phrenic and sympathetic nerves, and the former by its communication with the cervical and brachial plexuses is in intimate touch with the muscles of respiration and the integument of the chest. Counter-irritation is as efficacious here, in an idiopathic case, as in a traumatic synovitis.

The remaining topic of my subject, *internal counter-irritation* is one which I can do no more than touch on here, as it includes a whole department of therapeutics, capable, by the way, of considerable extension.

I rather fancy I am coining a phrase in thus speaking of ordinary medication, but, from what has already been said, the analogy must be sufficiently clear. The mode of action, moreover, seems to be identical, though the place of application is necessarily different, that is to say, counter waves are sent out to those already existing and nodes are formed. The medium through which this is accomplished, is the blood, and since this

feeds many other parts than those irritated, the result is apt to be, more or less, systemic.

In only one of two ways can this be avoided, firstly, by using a drug which specifically affects a single nerve as Euphrasia, the trigeminus, or secondly, by employing minute doses of a more generally acting remedy, as Arsenic. For if a part of the nervous system is already irritated, it will respond to a dosage which would not affect it in health.

As an example, I shall take a single case, that of a child with henteric diarrhoea. Hyperæsthesia of the intestines is here so marked, that the presence even of food, is resented. The half-digested stools and watery evacuations prove this. Of late years, considerable success in the treatment of these cases has been reported, by the use of minute doses of arsenite of copper. Now arsenite of copper is surely an irritant to the intestinal mucous membrane, and if it acts in the way it is said to act, there can be but one reasonable explanation. The branches of the sympathetic and vagus nerves are evidently vibrating at a great rate, as is shown by the increased metabolism. The gray-matter of the cord, in which, sooner or later, both these nerves end, is found largely impregnated with arsenic in cases of chronic arsenical poisoning. This is just where, in the large majority of cases, reflex acts occur. Hence, if this is irritated by arsenic at the same time that a peripheral impulse is travelling up an afferent nerve, a greater or lesser number of nodes must be formed in the efferent nerve, with its accompanying result of decreased metabolism. The antiseptic powers of arsenic are not sufficient to my mind, to account for the results apart from the reasons given.

### Clinical Department.

#### SOME NOTES ON THE PRESENT EPIDEMIC OF INFLUENZA.

BY ALLEN GREENWOOD, M.D., WALTHAM, MASS.

The following observations are taken from my notes on a number of cases, and from my own unpleasant acquaintance with "Grip" in Waltham.

The attack usually begins with a feeling of depression, followed by dull pains, often becoming severe in the limbs and back, and often with chilly sensations. In almost every case these symptoms have been followed in twenty-four hours by a severe headache and a feeling of soreness in the throat, with painful deglutition. The inflammatory process soon extends to the larynx, and the patient becomes hoarse or loses the voice entirely; and it is here that the most painful part of the attack (to myself and several others) has been, for the pain about the region of the larynx has been intense, resembling the pain of a bad toothache or earache.

In about twenty-four hours after the beginning of the throat symptoms, the patient begins to cough, and soon there comes a feeling of tightness and soreness about the chest, the feeling of tightness often amounting to a suffocative sensation that is very distressing. The cough is accompanied by a varying amount of expectoration of a white or yellowish-white frothy material, which is occasionally streaked with blood. The expectoration becomes much less on the second or third day after the cough begins, and the dry cough remaining may last a week or more.

There is often more or less coryza, and there was in most of the cases a symptom I had never seen before, namely, a severe, dull pain over the frontal sinuses, probably due to a congestion of the membrane lining the sinuses. In my own case this pain lasted several days, and was accompanied by a marked swelling and tenderness of the integuments over the sinuses.

The evening temperature when first taken, usually after the throat symptoms were well established, varied between 100° and 103° F. It remained about the same for twenty-four or forty-eight hours, with morning remissions of one or two degrees, and then fell by lysis reaching normal on the fifth or sixth day. Two of the cases were followed by acute otitis media, requiring paracentesis and the usual after-treatment for such cases.

The attack usually leaves the patient very weak, and it is often several weeks before full health is regained.

Physical examination of the chest did not show much beyond the few usual signs of a acute bronchitis of the larger tubes. In examining the throat I was struck by the absence of any follicular deposits, the appearances being invariably those of acute inflammation of the tonsils and pharynx, the surface of the whole region posterior to the anterior pillars of the fauces looking like raw beef.

In speaking of treatment, I shall only mention those things which in my few cases have given the most relief.

In no case has treatment been begun on the first day; but for the severe headache of the second day antipyrine, in fifteen-grain doses, has served me well, and given much relief to patients.

For the sore throat and painful laryngitis, hot, moist applications are indicated, either in form of poultices or cloths rung out of hot water; and the relief thus afforded, as I can testify, is very grateful.

For the feeling of soreness and tightness in the chest, nothing gave so much relief as a clear mustard paste to the front of the chest, left on fifteen or twenty minutes till the skin was well reddened.

At night the patient should take ten grains of Dover's powder, which will probably ensure a good night's rest; and this may be repeated the following night.

As the expectoration ceases, the cough becomes useless and distressing to the patient, and to relieve this one of the anodyne cough mixtures may be given. I have had very good success with a combination of morphine and hydrocyanic acid, as in the following:

R Morph. sulph.	. . . . .	gr. ii.
Ae. hydrocyan. dil.	. . . . .	3℥.
Syr. tolu	. . . . .	3℥i.
Syr. simp.	. . . . .	ad. 3iv. M.
Sig. Teaspoonful every three hours, for cough.		

This will usually stop or relieve the cough so that it need not be taken more than two or three times a day after the first few doses. One patient did not follow directions, but continued the medicine after the cough had stopped until such marked physiological effects of the hydrocyanic acid appeared as to frighten her.

For the painful congestion in the frontal sinuses, cloths rung out in hot water and laid on the forehead gave relief, as did also antipyrine used in fifteen-grain doses.

From other physicians here I learned that the type of the disease as given above is similar to that observed by them.

## Reports of Societies.

### BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

G. G. SEARS, M.D., SECRETARY.

REGULAR meeting, Monday, February 9, 1891, DR. A. H. NICHOLS in the chair.

#### ORAL COMMUNICATIONS.

DR. NEWELL: I would like to call the attention of the members of the Society to something with which they are already probably familiar, and that is styrene. I was especially led to do this by a new preparation of it which has proved, as far as I have used it, a very valuable one. I happened to think of it as a substitute for iodoform in combination with collodion. This preparation is styrene collodion, the strength being about one part to eight. As a protective film it is absolutely certain from the germicidal standpoint. There has recently been, especially in Europe, quite a little attention given to styrene, and it has proven of great value there as an antiseptic, stopping the secretion of pus where other powerful germicides fail to do so. In Lehn and Finck's notes on new remedies, there are two columns on this subject. There is one statement of particular interest by Dr. Cheltoff, of cases in which he has used a solution with twenty grains of styrene to the ounce of alcohol, with great benefit in otitis media, where all other antiseptic solutions had failed to produce any good effect. Thinking the cessation of pus formation might be due to the alcohol, he omitted the styrene from the solution, and the pus again appeared. It proved to be an excellent analgesic in all his cases.

This does not make a very expensive preparation, the price of styrene having been reduced from \$2.00 to \$1.75 per ounce, which corresponds to the cost of iodoform when it was first received. It has all the advantages of iodoform and is absolutely non-toxic, has been given in one-half ounce doses to small dogs without toxic effects, and has never produced toxic symptoms in patients where it has been used.

DR. W. N. BULLARD and DR. E. H. BRADFORD reported:

A CASE OF CEREBELLAR TUMOR; OPERATION; HEMORRHAGE FROM DEFECT OF OCCIPITAL BONE; DEATH; GENERAL REMARKS.

DR. BRADFORD: I wish to allude to one or two things which occurred during the operation which suggest the difficulty of operating upon cerebellar tumors. As there have been so very few of these operations we have very little to guide us, and I confess that when I decided to undertake the operation which Dr. Bullard suggested, I at first felt a certain amount of apprehension, but I think after a little experience one can feel that there is no more difficulty in trephining in the cerebellar region than in trephining elsewhere, provided the landmarks are carefully borne in mind. The only difficulty is that the neck muscles have to be dissected down almost to the foramen magnum, which in itself must occasion some discomfort to the patient.

Another point which was manifest in this case as in one or two of the other cases which I have had was the disadvantage of ether as an anesthetic. Mr. Horsley prefers chloroform. I had supposed this was

due to the English prejudice in favor of chloroform. I think that most American surgeons have used ether. In each case I have seen there has been a good deal of venous bleeding in the incisions on the scalp at the commencement of the operation. When ether is given, a certain amount of asphyxiation may occur at the commencement of the anesthesia from irritative spasm of the larynx. This would be less likely to occur with chloroform, which is usually given more carefully. Furthermore, the stimulating effect on the circulation with ether is greater than with chloroform. For these reasons it would seem that Mr. Horsley may be correct, and that chloroform is the better anesthetic.

Another point in regard to the technique of the operation which I have not seen alluded to, and which seemed to me of importance, is the position of the patient when operated on. The operation has to be done with the patient on the face and in such position that the trephine should be applied to the lower part of the skull. It should be done with the patient partially upright, so that there may be as little blood in the head or in the scalp as possible. For that reason it seemed to me that in another operation I should place the patient upon the board which was inclined at an angle to the table. The patient should be with the chest downward on this board, and a hole should be cut for the mouth so that the patient could lie on the face, and the anesthetic be given through the hole. This would give the surgeon an opportunity to work in a more convenient position, and with chance of the least possible loss of blood from the nerve centres and consequent shock.

In regard to the nature of this individual specimen, which is surgically of considerable importance, I can say nothing. It was manifest that it was a congenital affection. There was no evidence of any disease in the bone after operation. It will be noticed that the two foramina which are mentioned as first bleeding at the time of the operation are much larger than those ordinarily seen in normal bone. It would seem, therefore, that near the median line in this individual case, there was a defect of ossification around the small veins which communicated with the sinuses, and if any generalization can be made from one case it would be that in future cases for operation for cerebellar tumor the median line should be avoided as far as possible. The periosteum should not be stripped back as is done in other operations in cranial surgery, and the occipital protuberance should be particularly avoided.

DR. PUTNAM: I think this paper is a real addition to the literature of the subject. The question of operation in many cases of cerebral tumor and especially cerebellar tumor, is one which is largely decided by the personal equation and the temperament of the operator and the patient. For my part I fully sympathize with those who recommend operations in doubtful cases where there is a possibility of help. I shall not forget two cases of my own in both of which the tumor could have been removed could they have been found. In one of the cases a large hard mass lay entirely outside of the brain and only compressed it, and was attached by a very slender pedicle to the bone. The only localizing symptom was a slight degree of facial paralysis. If this indication had been followed and the patient given the chance of benefit, I think a cure would have resulted. In the other case the tumor was not strictly cerebellar but lay be-

tween the cerebellum and the pons. In that case the pedicle was slender, and a great part of the tumor lay perfectly loose in the cavity of the fourth ventricle.

I do not think it is realized what an immense mass of facts we must accumulate before we arrive at anything like even semi-scientific knowledge on this subject, and those who assist in the accumulation of this material and are willing to take the necessary risks are certainly benefactors.

As regards the functions of the cerebellum, most of the effects are wrapped in obscurity. Dr. Spitzka has made a suggestion which I think interesting and which possibly bears on the occurrence of mental symptoms, namely, that the cerebellum acts as a sort of reinforcing organ to the brain. It is not absolutely necessary to any function, but reinforces many functions, perhaps especially the more delicate ones. He thinks it very likely that the several senses may be made to perform their functions more accurately through the agency of the cerebellum. Dr. Gowers has pointed out that the cerebellum receives only afferent fibres, and could not act strictly speaking as a motor organ, and motor function must be performed indirectly.

With regard to the occurrence of optic neuritis which Dr. Ballard speaks of as very important, we have recently had a case at the Massachusetts Hospital which seems to me a very valuable one from that point of view. The case is that of a little Italian child three years old, who fell from a window, and two or three weeks after that symptoms began for which she came to the hospital. When I saw her she could not be said to have a reeling gait because she could not walk alone, but she threw her legs out, when supported erect, in a very awkward way. Except a cut there was nothing to see. It had a sort of apathetic behavior that Italian children often do have. For the sake of satisfying myself whether there was any cerebral disease I examined the eyes, and found well-marked optic neuritis, which was confirmed by Dr. Wadsworth. There was no headache. The child was removed to the medical side, gradually got worse and died, and at the autopsy nothing at first was found, no sign of pressure. The pons had a translucent look, and on microscopic examination it was evidently the seat of an infiltrating glioma, which involved the pons to a considerable extent and a portion of the cerebellum. Portions of the corpora quadrigemina were also involved, and it seemed more than probable that the optic neuritis was due to inflammation of the commencement of the optic tracts. The case also illustrates the fact that glioma may grow tolerably rapidly. In this case the symptoms did not exist more than two months. It is interesting as one more case to add to those that Dr. Starr speaks of, where tumor in the cerebellar region seems to originate from injuries.

In the case reported to-night I wondered if it was possible that this perforation of the bone could have been due to the presence of the tumor. Dr. Hale White's paper on thinning of the bone suggests itself. The thinning is sometimes general, sometimes very local, and not necessarily over the seat of the tumor, and the tumor happens to impinge on the skull.

As to prognosis, I think we must admit that in a given case the chances would be a good deal less than the statistics of Dr. Hale White and Dr. Starr would indicate, because many mischances are possible

in the operation, and so many tumors are difficult to remove.

DR. BRADFORD: In this individual case I must say that the presence of the tumor did not appear to have anything whatever to do with it. It not only was not adjacent, but there was no pressure on the dura in the portion where the hole existed, though there was pressure on the dura in the portion below. The bone was not made thin; it was thick. The hole has nothing of the shape following thinning from pressure of a tumor. The opening seemed to be connected almost directly with the torcular Herophili.

DR. KNAPP: I was rather surprised a while ago in looking over the statistics of a number of cases of brain tumor at the City Hospital—cases which I had collected from the autopsy records where the tumor was found at the autopsy—to find that out of thirty-eight cases there were twelve, I think, where the tumor had apparently given rise to no particular symptoms, and the patient died of some other disease. Two of those cases were of tubercle in the brain where there was also tubercular meningitis, so that the symptoms might have been from the tumor or from the meningitis. The other cases were tumors in various regions of the brain, some of which were apparently cases of long standing, and the patients had died of phthisis or pneumonia or renal disease,—something independent of the tumor. That is of some value, and comes out more strongly in this collection of a few cases from autopsy records than from any collection of published cases of brain tumor, as showing that there is a certain percentage of cases where, in spite of the presence of a tumor, the patient experiences no material inconvenience. I think, however, we may say of the cases where a tumor exists in the brain that, although a certain percentage of them go on without symptoms, the patient dying of some intercurrent disease, yet where the symptoms are definite, the prognosis is practically hopeless. Another point is that the cases suitable for operation are less than figures based on published cases which have been reported as showing definite symptoms, would show.

I was also surprised, in going over most of the reported cases (some thirty-five), to find that the successful operations for removal of a tumor formed about sixty-five per cent. of the cases. On the contrary, in the cases where the tumor has not been removed for any reason the mortality seems very much greater. I had collected nine cases, of which seven proved fatal where the tumor had not been removed. Since then there have been some half-dozen other cases reported making, I think, a total of six out of fifteen where the patients had recovered. In regard to the operation for cerebellar tumor, I understood Dr. Ballard to allude to a case by Mordell. I had sent to me some time ago the record of a case of Mamsell of New Zealand, a case of enormous hydatid cyst, about four inches by three, in the left-hand side of the subtentorial space, which had pushed the cerebellum way over on the right. The patient was a young man of about twenty, I think. The symptoms were those of headache, vertigo, not much vomiting apparently, although there was some, very marked retraction of the neck, the reeling gait, which was interesting as confirming Dr. Ballard's point, that the gait was not necessarily a symptom of disease of the middle lobe, and an enormous dilatation of the veins of the head. He was operated upon in the ordinary method with this exception: they put the man upon the table with the whole upper part

of his chest and face projecting over the edge of the table, then bent his head straight down and an assistant sat underneath to hold the head, and he operated in that way. They drained out this cyst, put in a drainage-tube, and the man made a complete recovery. Before the operation he had lost sight, hearing and taste. He recovered every thing but his sight.

The question of trephining to relieve pressure, advised by Mr. Horsley, I have already spoken of at another society meeting here; and I have recently got Dr. Bradford to operate successfully on such a case which I shall report later.

DR. C. F. FOLSON: By Dr. Bradford's kindness I saw this case at the City Hospital, and it seemed to be one of cerebellar tumor either large or multiple; and I agreed that its locality was such that it could be definitely ascertained and admitted of surgical interference.

DR. NEWELL: It seems to me there is one advantage in operating in the cerebellar region that has not been spoken of, and that is the favorable site for drainage; another thing of advantage is that you eliminate the difficult problem of location, because there is only a small area over which you can safely trephine, and go in to do the best possible in an individual case.

I should like to ask Dr. Bradford as to the amount of bleeding and the cause of death.

DR. BRADFORD: The amount of blood lost was not large, but in my opinion the sudden loss of blood from the torcular Herophilli causing cerebral anemia and shock was the cause of death.

DR. C. F. FOLSON then reported four cases of intracranial tumor, of which two were cerebellar, where the symptoms were very urgent—partial or total loss of vision, severe convulsions, violent headache, impaired consciousness, mental failure—in which there had been such marked improvement without surgical interference, and in which the general condition of the patients had become so comfortable, that an operation could not now be advised. He regarded many of the statements of results from trephining in cerebral tumors as altogether optimistic, as in reports of the benefit of medical treatment in epilepsy, and thought the prognosis without operating much less unfavorable than it had been represented. Such cases as he reported, he believed, should be kept in mind when surgical measures were considered.

#### ANATOMICAL SPECIMENS.

DR. BRADFORD showed a bullet recently removed from the lower part of the tibia, from a pistol wound in 1865. The bullet was imbedded in the tibia. The wound healed, and the man had no trouble from it. There was left hardly a scar. Three years ago he began to have a great deal of neuralgia in his foot, and came to the City Hospital incapacitated for work, and a candidate for one of the soldiers' homes. I trephined over the lower end of the tibia and found no bullet, and it was only when I had divided the lower portion of the tibia at half its thickness that I struck this bullet, which was removed. The pain has ceased, and the wound healed by first intention, the blood-clot becoming organized. In three weeks after the operation the man was going about on crutches, and is able to bear his weight on his foot.

Dr. Bradford also showed some fragments of bone from a case of compound fracture of the parietal bone. The boy fell eighteen feet, and struck on the corner of

a projection, making a multiple fracture over the parietal region, splintering the bone in several directions. He was conscious, and there was a slight opening in the scalp. An incision was made and a large comminuted area, three inches in diameter found. The dura was not affected. The loose fragments which were irregular were removed. The wound healed by first intention, without any symptoms of meningitis. This case is interesting as showing that a free incision, laying bare the seat of the fracture, exploring carefully, is in itself an operation of comparatively little danger provided the dura has not been opened.

### Recent Literature.

*Leçons Cliniques sur les Maladies de l'Appareil Locomoteur (Os, Articulations, Muscles).* Par le Dr. KIRMISSON, Prof. Agrégé de la Faculté de Médecine, etc. Avec 40 figures dans le texte. Paris: G. Masson. 1890.

This volume is a publication of 539 pages, and contains the lectures on Clinical Surgery relating to the organs of locomotion delivered by its author at the Hotel Dieu, and apparently intended by him to be used as a book of reference by his students. The work, as indicated by its table of contents or an extended perusal, does not seem to be a systematic or complete treatise. It is rather a collection of subjects, some belonging to general, some to orthopedic surgery. For example, fourteen pages are devoted to the description of calcified fibroma of the abdominal wall. The first three chapters treat of osteitis and osteomyelitis. The fifth to the fourteenth inclusive, are devoted to joint disease. The sixteenth to the twenty-ninth to various subjects, among which are torticollis; dislocation of the shoulder; ankylosis following fractures treated by resection; pseudoarthrosis; radial paralysis; badly united fractures; synovial cysts of the wrist; exostosis of the great trochanter and the treatment of fractures of the patella. The remaining chapters treat of orthopedic work. The book is of interest, and contains considerable valuable material, but will probably never become a popular work, or compete with the works on general or orthopedic surgery already published, especially some of the later treatises.

*The Uses of Electrolysis in Surgery.* By W. E. STEAVENSON, M.D., Cantab., M.R.C.P., in charge of the Electrical Department at St. Bartholomew's Hospital; Physician to the Grosvenor Hospital for Women and Children; late House Surgeon to St. Bartholomew's Hospital and to the Hospital for Sick Children, Great Ormond Street. London: J. & A. Churchill. 1890.

Electrolysis is one of those remedies which the profession has looked at askant from its never having been placed upon a definite scientific basis. Dr. Stevenson has devoted a large amount of time to an investigation of this subject, and while speaking with all the hope of an enthusiast, has placed in this little volume a clear account of the uses of electrolysis in surgery. Any surgeon will find here a clear and reliable account of the technique of the application of electrolysis. This fills a need, and we cordially recommend the book to practical surgeons.

DAMRELL & UPHAM,  
283 WASHINGTON STREET, BOSTON, MASS.

THE FIFTH FRENCH CONGRESS OF SURGERY.

THE Fifth French Congress of Surgery, held at the *Ecole de Médecine*, Paris, March 30th to April 1st, was noteworthy by reason of the large number of representative men there present and the importance and interest attending the subjects there discussed.

One of these was that of craniectomy for the microcephalus, for children with arrested cerebral development, and for young subjects presenting, either with or without epileptic crises, disorders of cerebral origin. Many of these cases would seem to be in common parlance, skull bound, and an operation which consists of opening up the cranial sutures or removing portions of the cranial bones so as to liberate the compressed cerebrum and enable it to expand and develop seems to find theoretical justification. The results of this operation as performed by Lannelongue, Anger, Larabrie and others, and stated at the French Congress, appear to have been such as to warrant further trials.

Lannelongue reported twenty-five cases coming under his observation where this operation was performed. In microcephalus proper, from the examination of numerous crania he has noted an advanced state of ossification of the sutures, with smallness of the fontanelles. In one new-born infant, the fontanelles were closed at birth. Reasoning that if more space were given to the brain the microcephaly would disappear, he makes along the median line of the skull a long and narrow incision corresponding to the sagittal suture and extending from the frontal to the occipital sutures. Sometimes a transverse craniectomy is made along the frontal bone. Care is taken not to wound the longitudinal sinus, which may be detached along with the dura. In some cases, Lannelongue performs *craniectomie à lambeau*: that is, he makes an incision through the scalp and pericranium just to the left of the sagittal suture, and removes with the trephine, a small circle of bone about a finger's breadth from the suture. From this, as a starting point, a narrow strip of bone nine centimetres long and six millimetres broad is cut

away, parallel with, and to the left of the sagittal suture, the aperture in the skull extending from the coronal to the lambdoidal suture. The dura mater is left intact, the scalp wound carefully closed with sutures, without a drain, the periosteum not being replaced across the bony defect."

Of the twenty-five operations, Lannelongue reckons twenty-four recoveries and one death from septicæmia. As for the ultimate results, these are said to be amelioration in a considerable number of cases, intelligence and the power of walking being improved.

"If the premature synostosis of microcephaly is the primary condition, the operation seems to rest on a sure pathological basis."

In other morbid conditions, as in thickening of the bones of the cranium with premature closing of the cavity, in some cases of focal epilepsy in defective cerebral development from "obstetrical compression," hamatomata, circumscribed pachymeningitis, serous cysts of the cerebrum, etc., the operation is said to be indicated, and the results are sufficiently encouraging.

A case of craniectomy in which Lannelongue's method was followed, was reported at the same meeting by Anger, others were reported by Larabrie and Marinoury. The latter regards any operation which promises the least amelioration in an idiot as of importance.

Professor Verneuil deems the operation as one destined to save more than one unfortunate child otherwise doomed to a precarious and unfortunate existence, and asserts that it is a great triumph for French surgery.

At this Congress, Thiriar, of Brussels, mentioned a case of intestinal obstruction by a calculus supposed to have been primarily of biliary origin, having a basis of cholesterine. Laparotomy was performed and the obstructing cause discovered; the intestine was opened, and the calculus removed, then the intestinal wound was sewed up with chromicized catgut. The after results were favorable.

Breckel, of Strasburg, read notes of sixty-one cases of resection of the knee-joint; fifty of these resulted in permanent cure. This operation is indicated whenever there is suppurative fungous arthritis with fistula; in fact, according to this authority, every case of tuberculous arthritis which has resisted methodical treatment for several years, should be treated by resection, even if there be tendency to cure. This kind of arthritis rarely gets well, and the surgeon, after practising immobilization for several months, after having subjected his patient to cauterizations, compression, etc., will find it for his interest to perform resection. Resection is also applicable to arthritides which have given rise to an ankylosis in a bad position.

The subject of *traumatic aphasia treated by trephining*, and of cranial surgery generally was discussed. The following symptomatic group is said to indicate an effusion of blood, necessitating trephining: hemiplegia and stertor with certain local phenomena such as swelling, pain, and ecchymosis in the tempero-mas-

toid region. Stertor is a sign of compression, of paralysis; may be due to an effusion, but many other causes may produce it. Hemiplegia is of more value, for it is a symptom of cortical localization. It may be the result of a destructive contusion of the cerebral pulp with little effusion of blood. The ecchymosis of the temporo-mastoid region presupposes a fissure of the temporal bones, and is sometimes produced by external violence.

Duret spoke of traumatic aphasia with semi-parietic troubles and hemi-anæsthesia, and reported a case of motor aphasia following a fall on the head; the paralytic phenomena and the aphasia came on gradually, nearly a fortnight elapsing before any marked change was noted. Taking into account the motor aphasia, the seat of the headache, the right-sided parietic manifestations which were limited principally to the head and face, Duret diagnosticated a traumatism of the left hemisphere in the region of the third frontal convolution and the lower part of the ascending frontal and parietal. Believing that there was in this spot a large meningeal hæmorrhage, he decided to trephine, and removed a large ring of bone in front of and above the lower extremity of the Rolandic line, six centimetres above and in front of the external auditory meatus. A large blood clot was found under the dura, which when incised, gave issue to two tablespoonfuls of blood. The result was favorable, the paralysis disappeared, and intelligence returned; the patient resumed work. The aphasia, however, continued, though the patient could express himself better than he could before the operation. This patient eventually died of meningitis from drink. Duret also reported a case of traumatic epilepsy where trephining was successful, and was followed by Jeannel, of Toulouse, on the subject of Jacksonian epilepsy, with the report of a case cured by trephining; by Broca, on the "Indications for Trephining," and by others.

We have only touched upon a part of the topics which came before this busy Congress, and we have omitted some that were equally important with those that are mentioned.

#### ANNUAL REPORT OF THE BOSTON CITY HOSPITAL, 1890.

THE Superintendent of this Hospital, in summing up his report, says: "The year's work has been arduous, and has shown important results. The number of patients has been larger than any previous year, and the character of the care and medical nursing has reached a high degree of excellence. A new out-patient building has been occupied, and the work organized on a better and more methodical basis. A Convalescent Home has been purchased, adapted to its purpose in a liberal and satisfactory manner, and occupied within the year. A medical library building has been planned and constructed. A playstead has been arranged for the children on the roof of the large operating-room. A new surgical out-patient depart-

ment is well under way. The staff services have been increased in three departments; three assistant visiting surgeons, three physicians to the Convalescent Home, and the house staff increased four in number. This indicates some of the advances made during the year. It has brought much extra labor, aside from that ordinarily attendant upon so large a hospital, practically always full."

The number of hospital beds remains the same, 480, but it is not adequate to the increasing demand. The admissions during the year were 6,437, of which 3,332 were medical, 2,797 surgical, 207 contagions, 80 ophthalmic, and 57 aural.

In this hospital, as usual, the medical patients outnumber the surgical, whereas at the other large hospital of Boston—the Massachusetts General—the reverse is the case. The average stay of each patient in the hospital was 20.46 days. The average cost of each patient per week was \$11.20, a cost slightly in excess of the average for the preceding year.

The total number of out-patients was 12,983, classified as follows:

Medical Diseases . . . . .	2,623
Surgical Diseases . . . . .	5,744
Diseases of the Eye . . . . .	1,421
" of the Ear . . . . .	532
" of the Skin . . . . .	841
" of Women . . . . .	639
" of the Nervous System . . . . .	489
" of the Throat . . . . .	700

The Convalescent Home will accommodate thirty-six patients, is intended for women, girls and young boys; and while patients may pay their board, as at the hospital, no private accommodations are available. Good food, pure air, amusements, rest, reasonable occupation, exercise, and in the summer season all the advantages of open-air country life are anticipated from this new departure for patients recovering from acute illness.

The Playstead for Children on the roof of the operating-room has a floor-space twenty-four feet by eighteen feet, surrounded by heavy wire guards. It is practically a play-room in the open-air, commands an extensive view, and in summer with the aid of awnings, hammocks, easy-chairs, boxes and vases of flowers is a very desirable addition as a means of physical improvement.

The Training School for Nurses has just closed its thirteenth year. The school has graduated 242 nurses since its formation, and 30 during the past year. At the end of the year 80 nurses were in attendance.

The report closes with an eloquent address by Dr. T. M. Rotch to the graduating class of the training school.

#### THE RECENT DEATH-RATE OF NEW YORK.

THE largest mortality of the present season was reported during the week ending April 18th, when the number of deaths reached 1,317. While the total for the following week was 139 less, on one day, April 20th, the number of deaths was 251; which exceeds

by one the largest record for any single day during the influenza epidemic of January, 1890, and has not been equalled since the year 1872. Of these deaths, 157 were from diseases of the respiratory organs, and of the latter, 57 were due to pneumonia.

After the 20th, the death-rate greatly diminished; and the total mortality of the week ending April 25th, was 1,208, representing an annual death-rate of 37.75 per thousand inhabitants. Two hundred and seventy-two of the deaths were attributed to pneumonia. This is 157 above the average number of deaths from this disease which occurred during the corresponding week in the past five years. Bronchitis caused 86 deaths, which is eight less than the preceding week, but 44 above the average for the corresponding week in the past five years.

#### MEDICAL NOTES.

**THE JOURNAL OF GYNECOLOGY.**—The first issue of a monthly journal with the above title, to be devoted to gynecology, obstetrics and abdominal surgery has appeared this month. It is published in Toledo, Ohio, and edited by Charles N. Smith, M.D.

**THE CLIMATOLOGIST** is to be the title of a new monthly journal, to be first issued probably in July. It is to be devoted to the relation of climate, mineral springs, diet, preventive medicine, race, occupation, life insurance and sanitary science to disease. Special attention will also be paid to the subject of health resorts, descriptions of sanitoriums with special reference to their suitability to certain cases. It is under the editorial management of John M. Keating, M.D. of Philadelphia, Charles F. Gardiner, M.D. of Colorado Springs, and J. P. Crozer Griffith, M.D. of Philadelphia. The editorial office is in Colorado Springs, Colo.

**MILITARY SURGEONS OF THE NATIONAL GUARD.**—Dr. Nicholas Senn, of Milwaukee, is desirous of obtaining the name and address of every surgeon of the National Guard for the purpose of taking the preliminary steps towards the formation of a permanent national association.

**OPEN STREET-CARS.**—The health authorities of Brooklyn have carried out their threat against the open street-cars in that city. They have issued a formal order directing that the operation of such cars by railroad companies in the city of Brooklyn be prohibited from this date until May 15th, except on days when the temperature is not less than 70° Fahr. in the shade and then only between the hours of 9 A. M. and 6 P. M. It seems rather extraordinary that the intervention of the health authorities should be deemed necessary in such a matter.

**INFLUENZA.**—In New York and Brooklyn during last week several deaths were reported as due indirectly to the grip. More or less severe epidemics are reported from Fall River, and other New England towns, different parts of England, southern Europe, especially in Odessa and neighboring Russian cities.

In Boston the death-rate was only 21.7, with six deaths reported as due to complications of influenza. The *Sei-i-Kwai Medical Journal* announces that "Influenza seems to have declined since the spring season began, but small-pox which mostly attacks puberties, is still existing in Tokyo, causing three or four new cases every day."

**STATISTICS OF THE INFLUENZA.**—The Marine-Hospital Bureau has issued the following notice: "In order to secure proper records of the present epidemic of influenza, officers of State boards of health and all registrars are respectfully requested to transmit to this Bureau special statistics of cases of influenza, and deaths therefrom, from January 1, 1891, to the date of the report. The record will be of value exactly in proportion to the completeness of reports received. An epidemic so widespread, so serious in its effects, and of which the etiology is so obscure, must necessarily be one not only of the highest interest from a scientific point of view, but as well from the humanitarian standpoint of the public health officer. The Bureau, therefore, sincerely hopes that this appeal may not be in vain."

**THE RIGHTS OF A WET-NURSE.**—A contemporary reports a curious case which came before a court in New York City recently. A gentleman discharged a wet-nurse because she went out at night, and, on this and other grounds, was not satisfactory to him. The nurse brought suit for breach of contract, and asserted that as long as she supplied the infant with good milk, the father had no right to dismiss her. A pair of healthy-looking twins were produced in court as evidence of the superior lactogenetic capacity of the wet-nurse, whatever might be the irregularity of her habits or the delinquencies of her morals. The jury rendered a verdict for the plaintiff, and awarded her the full amount of her salary according to her alleged contract.

**FOOT-BALL ACCIDENT.**—Accidents and even deaths are not infrequently reported in the English papers as the result of the modern game of foot ball. Recently, in Birmingham, a player who had been apparently but slightly hurt was brought into the hospital some hours later in a state of collapse, and died on the following day. The autopsy showed that the pelvis of one kidney was blocked with a calculus, and the kidney itself contained a number of large cysts. The accident had ruptured this kidney, but as the cause of the collapse was not suspected, nothing was done.

**VENEREAL DISEASE AMONG FRENCH WORKMEN.**—Some statistics have recently been published by Dr. L. Fiaux, which would appear to prove that venereal disease is remarkably rare amongst workmen in the French capital. Dr. Fiaux examined a number of new hands on the Northern Railway of France, chosen from every type of skilled and unskilled laborer. One-fifth of the total had resided under one year in Paris. Out of the 2,488 workmen, the total amount of venereal disease appeared to be three cases of gonorrhoea and one of chancreoid with suppurating bubo.

**BROWN-SÉQUARD'S ELIXIR.**—It is reported that Brown-Séquard has communicated to the Society of Biology that recent investigations have convinced him that the fluid which is known by his name should be administered per rectum.

#### NEW ENGLAND.

**HOSPITAL IN SOMERVILLE.**—At a meeting of the subscribers to the Somerville Hospital Fund, the committee reported that an acre of land on Spring Hill between Summer Street and Highland Avenue, known as the Crocker-Tower property, had been bonded.

**MASSACHUSETTS ASSOCIATION OF BOARDS OF HEALTH.**—A quarterly meeting of this Association was held at Newton, yesterday. Dr. J. H. McCollom, of Boston, read a paper on "Suppression of Infectious Diseases," which was discussed by Dr. F. W. Draper, of Boston; Dr. J. B. Field, of Lowell; Dr. W. H. Chapin, of Springfield; Dr. P. P. Comey, of Clinton; Dr. E. R. Cutter, of Waltham; Dr. C. H. Morrow, of Gloucester.

**RHODE ISLAND MEDICAL BILL.**—The State Senate has defeated the bill to regulate the practice of medicine in Rhode Island.

#### NEW YORK.

**TYPHUS FEVER.**—A case of typhus fever was found among the steerage-passengers of the steamship *La Bourgogne*, of the French Line, which arrived on April 18th. The patient was a Syrian who came from Alexandria, Egypt.

**IMMIGRANTS AT QUARANTINE.**—Including the *La Bourgogne's* passengers, there are now detained in quarantine no less than 1,490 immigrants, which is a considerably larger number than have been there at any one time for many years. Six hundred and ninety-six of them were steerage-passengers on the German steamship *Fulda*, on board of which small-pox appeared during the voyage to New York. The steamship companies are required to pay for the maintenance of their steerage-passengers during their detention at Quarantine.

**YELLOW FEVER.**—The United States and Brazil Mail steamship *Advance*, which reached Quarantine on April 23d, had seven cases of yellow fever on board during her voyage from Brazil.

**SUMMER STUDIES IN BOTANY.**—A series of summer studies in botany has been inaugurated by the Torrey Botanical Club and the New York College of Pharmacy. The course is to consist of ten lectures and ten out-door excursions; and the lecturers will be Professors Henry H. Rusby, Henry Kraemer and Thomas Morong. The first lecture of the series was given on April 23d.

**AMERICAN MUSEUM OF NATURAL HISTORY.**—The widow of the late Dr. S. Lowell Elliot, the well-known entomologist, has presented his library, consisting of 11,000 volumes devoted to entomology and kindred subjects to the American Museum of Natural

History, on Manhattan Square. It is valued at \$15,000 and contains many rare and valuable works. The new quarters for the museum library, which will have accommodation for 52,000 volumes, are now nearly completed.

**STATE CARE OF THE INSANE.**—A public meeting under the auspices of the State Charities Aid Association is to be held on May 1st, at Chickering Hall, to commemorate the removal of over 2,000 insane persons from the poorhouses of the State, and the completion of legislation in their behalf (State Care Act of 1890, and State Care Appropriation Act of 1891), whereby, after a contest of four years' duration, the poorhouse system of caring for the insane has been abolished, and the State assumes henceforth the entire charge and maintenance of her dependent insane. The support of the community is also to be asked for other reforms undertaken by the Association, and among the speakers will be Ex-President Grover Cleveland, Bishop Henry C. Potter and Joseph H. Choate, Esq.

### Miscellany.

#### VIRCHOW'S SEVENTIETH BIRTHDAY.

SEVERAL of the pupils and admirers of Rudolph Virchow have united in appealing to the medical profession of the United States and Canada for contributions to the fund which is being raised in Germany, England, and, it may be said, throughout the world, as a testimonial to be given to Professor Virchow on his seventieth birthday.

The German committee proposes that the fund shall be used in procuring a large, gold portrait medal to be presented to Professor Virchow. Bronze replicas are to be given to each member of his family and to certain scientific institutions. The balance of the fund is to be transferred to Professor Virchow to be devoted to such purposes as he may see fit.

We take pleasure in calling attention to this subject once more (December 4, 1890, p. 459, and December 18, 1890, p. 600), and to the circular now issued by the American committee which offers our readers an opportunity to participate in the movement.

#### VIRCHOW TESTIMONIAL FUND.

The medical profession of the world has the opportunity of showing its gratitude to

#### RUDOLPH VIRCHOW

on his seventieth birthday, October 13, 1891.

It may well be said that there is no branch of medical knowledge which has not been made more fruitful through his labors. We appeal, then, with confidence, to the physicians of our country, to send forth a tribute which shall represent worthily America's obligations.

Contributions will be received by any one of the undersigned.

D. Hayes Agnew, Philadelphia.  
Gustav Baumgarten, St. Louis.  
William T. Belfield, Chicago.  
John S. Billings, Washington.  
H. C. Chapman, Philadelphia.  
Francis Delafield, New York.  
William H. Draper, New York.  
Reginald H. Fitz, Boston.  
James E. Graham, Toronto.  
Abraham Jacoby, New York.

Alfred L. Loomis, New York.  
William T. Lusk, New York.  
Henry M. Lyman, Chicago.  
William Osler, Baltimore.  
Wm. Pepper, Philadelphia.  
George Ross, Montreal.  
Nicholas Seim, Milwaukee.  
Fred. C. Shattuck, Boston.  
J. Collins Warren, Boston.  
Wm. H. Welch, Baltimore.  
James T. Whittaker, Cincinnati.

## PRESCRIPTIONS.

**FISSURES OF THE TONGUE.**—The following is given in *Médecine Moderne*, No. 10, 1891:

R Acidi carbonici . . . . . gr. xij.  
Tinct. iodi . . . . . ʒj.  
Glycerin . . . . . ʒj. M.  
Sig. Paint carefully in the fissures.

**EMULSION OF COD LIVER OIL.**—The *Formulary* advises the use of condensed milk as a vehicle for emulsions, and gives the following for cod liver oil:<sup>1</sup>

R Cod liver oil . . . . . 8 parts.  
Condensed milk . . . . . 3 parts.  
Glycerin . . . . . 3 parts.  
Distilled water . . . . . 2 parts.  
Oil of bitter almonds }  
Essence of wintergreen } . . . . . ʒj. q. s. M.

Rub the condensed milk in a mortar, adding the cod liver oil little by little, and finally the water and glycerin.

**TREATMENT OF WHOOPING-COUGH.**—Löffler recommends the following solution to be used in the treatment of whooping-cough:<sup>2</sup>

R Freshly prepared chloride of silver, 1½ grains.  
Water . . . . . 2 pints.  
Hyposulphite of sodium, a saturated solution. M.

Use by an atomizer, the liquid being directed into the pharynx. Repeat the application every two or three hours.

**COCAINE IN ASTHMA.**—C. R. D. Sylva<sup>3</sup> reports a case in which very severe attacks of asthma were in a few minutes entirely relieved by the following subcutaneous injection:

R Cocaine hydrochlor } . . . . . ʒj. gr.  
Morph. sulph. }  
Aque. destil. . . . . q. s. M.

## Correspondence.

## SUGGESTIVE THERAPEUTICS.

BOSTON, April 22, 1891.

MR. EDITOR:—Will you allow me to take up a small portion of your valuable space by a reply to an article on "Hypnotism," by Dr. Harold Williams, in your issue of April 9th?

I think that some physicians, who may not have studied the subject of suggestive therapeutics, may have been misled by some of Dr. Williams's remarks. In the first place, I wish it understood that I defend exclusively hypnotic suggestion as a therapeutic measure, laying more stress on the suggestion than on the hypnosis. I do not claim that suggestion during hypnosis is a panacea; but I do claim that it is of great value to physicians in some cases that drugs will not reach, and in other cases in which we do not want to give medicines. I have never heard of a case, nor have I seen a case, where therapeutic suggestion during hypnosis has been followed by any harm to the patient.

It is perfectly true, as Dr. Williams says, that patients are more easily hypnotized at each successive sitting. This, I am convinced, is not due to failure of will power, but is due to a gradual familiarity with a process of the mind, which was strange to employ at first. This mental process is simply the endeavor to banish all thought of our surroundings from the mind, and to fix instead the thought of sleep within it. Unless a person can perform this feat of mental gymnastics, he cannot become hypnotized. He thinks of nothing but sleep, he does not in any way give up his will to the operator.

Now in regard to Dr. Williams's picture of the *sauger*. As I have seen hypnosis induced by Dr. Hamilton Osgood,

and as I induce it myself, all the smiling and frowning by-play which Dr. Williams describes, together with passes, etc., are omitted, making the picture to be sure less brilliant in color. The operator requests the patient, who is seated in a comfortable chair or reclining, to dismiss all thought but that of sleep from the mind. He then generally endeavors to aid the patient's mind in its thought of sleep, by fatiguing the muscles of the subject's eye. This can best be done by holding up any bright object of small size so near the subject's eyes that convergence will tire the internal recti. The operator may or may not look at the patient; if he does, he certainly does not "fix his eye on the bridge of her nose," as Dr. Williams describes, as plainly that would tire his own accommodation and muscles of convergence. Now if the patient passes into the hypnotic state (whether he be hypnotized or whether he hypnotize himself is immaterial) the suggestions are made and the patient allowed to remain in the hypnotic state for a longer or shorter period.

In regard to the question of the patient's subduing his will to that of the operator. The patient's first objection, when it is proposed that he shall be hypnotized, generally takes the form of a question: "Shall I have to give up my will to you?" I say, "Not at all; it is no question of will, my will is no stronger than yours. I simply ask you to try to doze, and when you are in a sleepy state, which probably will be induced by your thinking of it and by the strain on your eyes, I will make these suggestions." I then tell the patient exactly what I shall suggest, using the same phrases that I later use when he is in the hypnotic state.

One can hardly, I think, see in the above sketch anything to show that the "nature of hypnotism," so practised, "is a fraud," or that, "because to practise it successfully one must deceive his patient and delude her into the belief that he can influence her or will her." It is absolutely unnecessary and wrong that the operator should be "mysterious," that he should make "impressive signs and should frown." It is quite untrue, according to my experience, that the "better actor he is the better will be his success." I agree thoroughly with Dr. Williams, that hypnotism repeatedly employed upon the same person to afford entertainment to onlookers is very dangerous to the mental stability of the person who is put through such laugh-provoking antics. I am so careful about this that I do not even say, "now you cannot open your eyes, or now you cannot put down your arm if I raise it." That the use of hypnotism will increase among the unqualified, if it is employed by physicians of good standing, does not necessarily follow. Thirty-five years ago the use of electricity was largely confined to quacks. Its use is now very widely spread among careful physicians who recognize that its use may be dangerous in unskilled hands. Yet I do not think its use has increased in the same ratio among the quacks as among physicians. The practise of hypnotism should, of course, be confined to those who have made a study of it; but what can we expect in a State where any one may dabble in the practice of medicine.

The fact remains the same, that in suggestive therapeutics, which to my mind is the only legitimate form in which we may employ hypnotism, we have a power potent for good; and I am anxious to see its use spread among the educated physicians of our country who are honorable men and who will not in any way abuse it. The legitimate use of hypnotism—suggestive therapeutics—is not harmful to the patient, because his will is in no way weakened; he is simply asked to think of nothing but sleep; he is cautioned beforehand that there is no question of his submitting his will to mine. I ask him to think of sleep. I might ask him for a light for a cigar, he may refuse either request. To the public it is not harmful. No quack will practise suggestive therapeutics. The quacks will misuse hypnotism, and the public will employ them, simply because the public is not yet educated to the degree that they can see the folly of employing the unskilled rather than the skilful and educated physician.

It is not harmful to the physician nor through him to the profession at large, because every physician who has made a careful study of the subject must know that anything in

<sup>1</sup> *Modern Medicine*, April 9th.

<sup>2</sup> *Medical News*, April 1st.

<sup>3</sup> *Indian Medical Gazette*, March 6, 1891.

the nature of acting, gestures, mysterious air or any effort in any way to impress on the patient the idea that the operator's mind is stronger than his is unnecessary and absolutely inadmissible. Finally, it is the experience of those who practise therapeutic suggestion that a sensible man makes a better subject than a neurotic, hysterical woman. I give my last case as one typical of the benefit to be derived from suggestion under hypnosis.

A. B., stenographer, referred to me for insomnia. The reverse of a hysterical or neurotic person. Well educated and bright. Since October, 1890, has been troubled with insomnia, which has steadily increased; has tried, under physicians in the South and here, most of the drugs employed in producing sleep, among them bromidia, chloral, antipyrin, phenacetin and sulphonal. Sleeps so poorly now that in spite of amusing herself with the theatre and evening entertainments to the point of fatigue, she can only get two or three hours' sleep. Says that in body she is perfectly well. Is discouraged and irritable from want of sleep, and has some worry, the nature of which was not inquired into. Thinking that in her exhausted condition a nerve tonic might give relief, she took strychnia in mixture. She slept well that night. The next night she was awake again, and her discouragement was pitiable. She insisted that something must be done. Thinking that her sleep before may have been due to the suggestion on my part that the strychnia would do her good, I proposed hypnotism. She objected on the ground that it was uncanny and that she must give up her will to mine. I told her that I had been hypnotized myself, and I explained as well as I could the mental condition of one in hypnosis. I insisted that in all probability my will was no stronger than hers, and that she was not to yield her will to mine, except that I hoped she would try to sleep if I asked her to. In short, I made no mystery of the subject whatever. She was hypnotized, was so little affected that she thought the only thing she noticed was that she could keep her eyes shut for full five minutes. I suggested that she should sleep that night. She went home and to bed at 10. Slept from 10.30 p. m. to 8.30 a. m., when she was waked up. I have hypnotized her three times since, using the formula that I had agreed with her to use: "Henceforward you will sleep like any well person, and no worry that you may have had in the past few years will keep you awake at night." She now sleeps well, and her gratitude is unbounded. There need occur but few cases, such as the above, in one's practice to convince one that the educated physician has another means in his power by which he can help his fellow men (or women, as Dr. Williams might put it). Very truly yours,

RUSSELL STURGIS, M.D.

NOTE.—Since writing the above, I have seen in the *London Lancet*, Nos. 3526 and 3527, two excellent reviews on late hypnotic publications. Their personal, I am sure, will interest many of your readers. R. S.

#### METEOROLOGICAL RECORD.

For the week ending April 18, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Date.	Barometer.	Thermometer.		Relative humidity.		Direction of wind.		Velocity of wind.		Wet'th.		Rainfall in inches.
	Daily mean.	Daily mean.	Maximum.	Minimum.	8.00 A. M.	8.00 P. M.	Daily mean.	8.00 A. M.	8.00 P. M.	8.00 A. M.	8.00 P. M.

Deaths reported 4,282; under five years of age 1,454; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fevers) 522, acute lung diseases 1,136, consumption 401, influenza 230, diarrhoeal diseases 135, diphtheria and croup 129, typhoid fever 67, scarlet fever 65, measles 48, cerebro-spinal meningitis 29, whooping-cough 25, erysipelas 19, malarial fever 4, puerperal fever 2, small-pox (Philadelphia) 1.

From typhoid fever Chicago 25, Philadelphia 22, Cincinnati 5, New York and Washington 3 each, Boston, Nashville and Lowell 2 each, Portland, Lawrence and Haverhill 1 each. From scarlet fever New York 37, Brooklyn 15, Chicago 6, Philadelphia 5, Boston and Chelsea 1 each. From measles New York 23, Chicago 10, Washington 6, Brooklyn 4, Springfield 2, Nashville, Lowell and Cambridge 1 each. From cerebro-spinal meningitis Chicago 10, New York 5, Brooklyn and Washington 4 each, Cincinnati 2, Philadelphia, Nashville, Worcester and Lynn 1 each. From whooping-cough New York 11, Chicago 4, Brooklyn 3, Philadelphia 2, Boston, Washington and Cambridge 1 each. From erysipelas New York 5, Chicago 1, Boston and Washington 3 each, Brooklyn 2, Philadelphia and Cambridge 1 each. From malarial fever New York and Brooklyn 2 each.

In the twenty-eight greater towns of England and Wales with an estimated population of 10,010,426, for the week ending April 11th, the death-rate was 22.9. Deaths reported 4,400; acute diseases of the respiratory organs (London) 464, measles 157, whooping-cough 117, diphtheria 40, scarlet fever 36, fever 30, diarrhoea 28.

The death-rates ranged from 18.3 in Brighton to 42.5 in Hull, Birmingham 22.3, Bradford 22.9, Leeds 26.8, Liverpool 24.0, London 20.0, Manchester 29.7, Nottingham 19.8, Portsmouth 34.2, Sheffield 24.8.

In Edinburgh 19.3, Glasgow 20.5, Dublin 30.6.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM APRIL 18, 1891, TO APRIL 24, 1891.

By direction of the acting Secretary of War, Major ALFRED A. WOODHILL, surgeon, is detailed to represent the Medical Department of the Army at the International Congress of Hygiene and Demography at its meeting in London, England, from August 10 to 17, 1891. He will leave his present station not later

than June 1, 1891, and will proceed to London. After the adjournment of the Congress, he will return to his proper station. While abroad under this order, and before returning to the United States, he will visit on official business such points in Great Britain as may be deemed necessary by the Surgeon General of the Army. Par. 17, S. O. 91, A. G. O., Washington, D. C., April 22, 1891.

By direction of the Acting Secretary of War, Captain WILLIAM F. KNEEDLER, assistant surgeon, is relieved from duty at Jackson Barracks, Louisiana, and will report in person to the commanding officer, Fort Logan, Colorado, for duty at that post, reporting also by letter to the commanding General Department of the Missouri. Par. 2, S. O. 88, Headquarters of the Army, A. G. O., Washington, April 18, 1891.

#### OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE, FOR THE TWO WEEKS ENDING APRIL 18, 1891.

**BAILHACHE, P. H.**, surgeon. To represent the Service at the annual meeting of the California State Medical Society, April 8, 1891. Detailed as chairman of Board for the physical examination of officers, Revenue Marine Service, April 14, 1891.

**VANSANT, JOHN**, surgeon. Detailed as chairman of Board for physical examination of officers, Revenue Marine Service, April 14, 1891.

**ACSTIN, H. W.**, surgeon. Detailed as chairman of Board for physical examination of officers and candidates, Revenue Marine Service, April 14 and 15, 1891.

**GASSAWAY, J. M.**, surgeon. Leave of absence extended five days. April 15, 1891.

**STONER, G. W.**, surgeon. To proceed to Alpena, Mich., on special duty, April 12, 1891.

**MCINTOSH, W. P.**, passed assistant surgeon. Detailed as recorder of Board for physical examination of officers, Revenue Marine Service, April 14, 1891.

**MAGRUDER, G. M.**, passed assistant surgeon. Detailed as recorder of Board for physical examination of officers, Revenue Marine Service, April 15, 1891.

**PERRY, T. E.**, assistant surgeon. Ordered to examination for promotion, April 6, 1891.

**WOODWARD, R. M.**, assistant surgeon. Ordered to examination for promotion, April 6, 1891.

**GOODWIN, H. T.**, assistant surgeon. Ordered to examination for promotion, April 6, 1891.

**VAUGHAN, G. T.**, assistant surgeon. Ordered to examination for promotion, April 6, 1891.

**GEDDINGS, H. D.**, assistant surgeon. Detailed as recorder of Board for physical examination of officers and candidates, Revenue Marine Service, April 14, 1891.

**PERRY, J. C.**, assistant surgeon. Detailed as recorder of Board for physical examination of officers, Revenue Marine Service, April 14, 1891.

**GROENEVELT, J. F.**, assistant surgeon. To rejoin station (New York), April 13, 1891.

**ROSENAU, M. J.**, assistant surgeon. To proceed to Cairo, Ill., for temporary duty, April 13, 1891.

#### OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING APRIL 25, 1891.

**D. MCURTREE**, medical inspector, detached from Navy Yard New York and to the U. S. S. "Lancaster."

**EDWARD KERSHNER**, medical inspector, detached from Marine Rendezvous and to Navy Yard, New York.

**C. P. HENDERSON**, surgeon, from Naval Hospital, New York, and to the Marine Rendezvous.

**JAMES E. GARDNER**, passed assistant surgeon, ordered to Naval Hospital, New York.

#### SOCIETY NOTICES.

**BOSTON SOCIETY FOR MEDICAL OBSERVATION.**—A regular meeting of the Society will be held on Monday, May 1, 1891, at the Medical Library, 19 Boylston Place, at 8 o'clock, p. m. Reader: Dr. Henry Jackson, "Stuttering."

JOHN C. MUNRO, M.D., Secretary.

**SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.**—There will be a meeting of this Section, at 19 Boylston Place, on Wednesday evening, May 6th, at 8 o'clock. Dr. A. T. Cabot will show three cases in which the Patella has been wired for Fracture. Dr. J. C. Warren will report two cases of Amputation at the Hip-joint. Mr. G. R. Tucker will (by invita-

tion) describe a new method for the Disinfection of Catgut. Dr. F. M. Briggs will read a short communication on "Torsion," and will show an automatic forceps for rapid torsion.

GEORGE H. MONKS, M.D., Secretary.

#### MASSACHUSETTS VOLUNTEER MILITIA. BOARD OF MEDICAL OFFICERS.

There appeared before the Board this day Lieutenant-Colonel Freeman C. Hersey, of Salem, who was duly examined and found qualified, as medical director, Second Brigade, April 21, 1891.

#### VIRCHOW TESTIMONIAL FUND.

Contributions have been made already, in and about Boston, by the following physicians:

George C. Shattuck, Boston	\$10.00
Henry W. Williams, Boston	5.00
J. Collins Warren, Boston	25.00
Henry F. Sears, Boston	25.00
George W. West, Boston	10.00
Amos H. Johnson, Salem	5.00
Walter Channing, Brookline	5.00
Frederick C. Shattuck, Boston	25.00
Hamilton Osgood, Boston	10.00
Francis H. Williams, Boston	5.00
Frederick I. Knight, Boston	5.00
Albert N. Bledgett, Boston	5.00
Francis H. Davenport, Boston	5.00
Henry O. Marcy, Boston	5.00
Reginald H. Fitz, Boston	50.00
Michael A. Morris, Charlestown	10.00
Archibald T. Davison, South Boston	10.00
John T. Bowen, Boston	10.00
James B. Ayer, Boston	10.00
Henry C. Haven, Boston	10.00

#### DEATH.

**WARREN TYLER, M.D., M.S.S.**, of North Brookfield, died of pneumonia April 18th, aged seventy-two. He served in the War as surgeon of the Thirty-sixth Regiment, and subsequently represented his town in the Legislature. He began practice in North Brookfield more than forty years ago.

## Original Articles.

## REPORT ON SEVEN CASES OF TUBERCULOSIS TREATED WITH PARATALOID.

BY DRs. C. M. JONES AND J. A. JEFFRIES.

THE cases mentioned below were treated by us in co-operation with Dr. Thorndike in the House of the Good Samaritan during the months of February and March. The parataloid was from two lots, that of Dr. Beach and that of Dr. Shattuck. No difference was noted between the two either in action or strength. Below are the notes of the cases as extracted from the house records and special notes made by myself.

CASE I. H. R., December 25, 1890. Child, female, seven years old, born in New Brunswick. Family history negative. Four other children in fair health. A maternal aunt died of lung trouble. Nursed as an infant, but had poor health. Has had measles and whooping-cough. Present trouble began three years ago, and was followed by considerable loss of flesh. No night cries till four weeks ago, since then much pain.

Notes from the Children's Hospital, where she was first cared for, were as follows:

February 15, 1890. Little swelling about joint; 45° permanent flexion; a few degrees of motion. Right leg 22½ in., thigh 11½ in., calf 8½ in.; left leg 22½ in., thigh 12 in., calf 9 in.

March 11, 1890. Abduction 7°; permanent flexion 25°. Right leg 21½ in., thigh 10½ in., calf 8 in.; left leg 22½ in., thigh 12½ in., calf 9 in. Hip-splint applied.

From this time on to time of entrance into the Good Samaritan, records show a varying state, which it is not necessary to give in detail.

On admission, hip painful; extension hurts back. Put to bed on a frame, with traction in line of deformity; pain is severe if traction is let up for a moment. Right leg 22½ in., thigh 12 in., calf 7½ in.; left leg 23½ in., thigh 12½ in., calf 9 in.

December 1st. Looks poorly; hip very tender. 6th. Much better; hip much less tender. 14th. Fly blister just over trochanter. 18th. Hip much less sensitive; abduction 10°.

January 15, 1891. Hip-splint applied and anchored with a weight. 25th. Abduction 15°; hip marked off in circles passing round the thigh over the joint. 26th. Hip more painful and sensitive; swollen about ten mm. along each of the circles. 29th. Child weighed 48½ pounds. Hip again marked off; upper circle measured 450 mm., middle 370 mm., lower 350 mm., thigh 300 mm. Swelling of a few days ago gone down. 30th. Parataloid (.0003) given at 9.30 a. m. Child bright all day. Slight rise of temperature in the evening. 31st. Comfortable just as usual; no tenderness in hip-joint. Circles measured 455 mm., 373 mm. and 350 mm.

February 1st. Gave .006 of parataloid. No temperature change all day; at night hip less sensitive. Circles measured 456 mm., 367 mm. and 337 mm. 2d. Hip less sensitive, and very slight rotation outward is now possible. Child bright. Circles 456 mm., 370 mm. and 334 mm. No perceptible rise of temperature. 3d. Gave .001 of parataloid. Still more rotation in hip. Circles 356 mm., 370 mm. and 345 mm. As yet no perceptible rise of temperature. 4th. As yet no reaction. Circles 355 mm., 378 mm.

and 345 mm. 5th. Gave .0015 of parataloid, which was followed by no change. Circles 354 mm., 374 mm. and 345 mm. 6th. Condition the same. 7th. Condition the same. Gave .002 of parataloid. Temperature rose slowly till 4 p. m., when it went up rapidly to 104.5° at 7 p. m. Child bright up to 7 p. m., when a sharp reaction came on, the pulse being intermittent and then (rate 145). A drachm and a half of brandy was administered, and the child spent a good night. During the period of high temperature the respiration was slightly increased in rate. 8th. Child bright; no local tenderness; slight motion both in abduction and adduction now possible. Circles 457 mm., 373 mm. and 345 mm. 10th. Gave .002; no reaction followed. Since commencement of treatment, to my mind, the child has lost color. There is slight swelling about joint, and motion is a trifle more free. 12th. Gave .0025 of parataloid; reaction followed, but less marked than on the 7th. Circles 453 mm., 380 mm. and 350 mm. 13th. Circles 445 mm., 375 mm. and 350 mm. 14th. Gave .003 of parataloid. No reaction followed. 15th. Circles 450 mm., 375 mm. and 350 mm. 17th. Gave .0035; a reaction (to temperature 103.5°, pulse 130, at 10 p. m.) followed. In the evening she complained much of her back. 19th. Gave .0035 of parataloid, which was followed by slight reaction. 21st. Gave .0036 of parataloid, of Dr. Shattuck's lot; no reaction followed. 24th. Found temperature rising, so gave .0036 again; slight reaction followed. 26th. Gave .0042; there was no change in hip; no reaction. 28th. Gave .0042; no reaction.

March 3d. Gave .0043; no reaction. 5th. Gave .0043. On this date the use of parataloid was given up, as none of us could see any beneficial effect.

CASE II. A. D., December 10, 1890. Female, twenty-five years old, single, born in Nova Scotia. Family history good. Never been sick until a year ago. Has had a cough for about a year, and more or less pain in left side. Lately has been short breathed. During the last nine months has lost about thirty pounds. Last June had two small hæmorrhages in one day. For the last two weeks has been in bed, during which time has had night sweats. No catamenia for a year.

*Physical Examination.*—Fairly well nourished. Weight 125½ pounds; rather pale and flabby; pulse 84; heart normal. Lungs: Front, slight impairment of resonance at apices and on clavicles; slightly more marked on right; respiration generally vesicular, with rather coarse râles over upper two-thirds of left and upper half of right; moderate concentration of voice under right clavicle. Back, dullness in supra-spinal fossæ and one-half down scapula; respiration vesicular, with abundant râles as far as angle of scapula on both sides; increased vocal resonance in both supra-spinal fossæ; most on right. Urine acid; color normal; specific gravity 1.023; no albumen.

January 25, 1891. Coughed considerably during day, but requires no medicine; sleeps well; general condition improved very much; weight 132½ pounds; râles over same area as before, but very few and scattered. 30th. Weight 133½ pounds. Temperature has been running uniformly at about the normal.

February 1st. Gave .0003 parataloid; no rise of temperature. 2d. Temperature between 97° and 98° during day; no other change. 3d. Gave .0006 parataloid; temperature rose to normal during rest of

day. 5th. Gave .001 paratoloid; no reaction. 6th. Weight 133½ pounds. 7th. Gave .0015 paratoloid; no reaction, but a very scanty sputa (No. 3, of Gafkey's table). 8th. Sputa No. 2 contained one mast cell. 10th. Gave .0025; no reaction. Sputa before injection. No. 0. 12th. Gave .0035 paratoloid. Sputa before injection. No. 2. So far no discomfort except slight tenderness and swelling at point of injection. 13th. Sputa No. 3; weight 137 pounds. 14th. Gave .0045 paratoloid; no especial symptoms; sputa No. 2. 15th. No. 2. 16th. No. 1. 17th. Gave .0055 paratoloid; no special symptoms; sputa No. 2, with small elastic fibres. So far can see no difference, except that there is now a yellow, thick sputa in place of none. 18th. Temperature reached 100° for the first time; no special symptoms; sputa No. 3, and one clump containing many hundred bacilli in a nest; catamenia for the first time in a year. 19th. Gave .0055 paratoloid; sputa No. 4. 20th. Weight 136 pounds. 21st. Gave .0066 paratoloid; mild reaction; temperature 101° at night; pain over diseased portion of lung. 24th. Gave .0066 paratoloid; sputa No. 2; no reaction. 26th. Gave .0078 paratoloid; no reaction. 27th. Temperature subnormal, fluctuating. 28th. Gave .009 paratoloid.

March 2d. Temperature in morning 96°, rising to 100° in afternoon. 3d. Gave .0102 paratoloid; sputa No. 0. 5th. Gave .01 paratoloid. 6th. Weight 134 pounds. 7th. Gave .0102 paratoloid; temperature rose to 101°, with considerable pain and tenderness over diseased portion of lung; increased pulse and respiration and aching in the limbs. 10th. Gave .01 paratoloid; no reaction. 12th. Gave .0108 paratoloid; no reaction in temperature; pulse rose to 120. 13th. Weight 135 pounds; apparently late reaction; temperature rising from 97° in morning to 101° at night. 14th. Gave .0108 paratoloid; no reaction; 15th. Patient coughs more than at entrance. Appetite has been poor for three or four weeks. Sleeps well. Chest front, resonance; right, dull in upper half; left, dull in upper third. Respiration generally vesicular; apex somewhat harsh; râles on both sides, as far down as fourth rib, increased in numbers by cough; concentration of voice under both clavicles. Back, dull in supraspinus fossæ, one-third down scapula. 17th. Gave .0120 paratoloid. 19th. Gave .0132 paratoloid; no reaction; sputa No. 3; stopped injection. For the last two weeks the temperature has fluctuated considerably, reaching 100° or 101° at night. The general state is not as good as when treatment was begun; the appetite is poor, muscular power diminished. 20th. Weight 133 pounds. 24th. Sputa No. 2. Patient was discharged at the end of the month certainly no better.

CASE III. M. B., December 23, 1890. Female, single, twenty-two years old, born in Nova Scotia. Family history negative. Last February had measles followed by lung fever, and did not get out of doors until the first of May. Says the pneumonia was on the left side. Has worked from May up to a week ago. For the last two years has been losing strength, and has had a cough with some expectoration, chiefly in the morning. Has not lost much weight; no hemorrhages. Catamenia rather irregular and scanty. When recovering from pneumonia had night sweats, but none lately. Appetite good. Sleeps fairly. Bowels constipated.

*Physical Examination.*—Weight 92 pounds; tem-

perature 99.6°; pulse 112; respiration 32. Depressions above clavicles most marked on the left. Chest, front: resonance impaired throughout left; most marked at apex; right, good. Respiration (left) faint, broucho-vesicular at apex; vesicular below, with abundance of fine and medium moist râles throughout. Concentration of voice at apex; right, vesicular without râles. Back: resonance impaired over upper half left and in right supraspinus fossæ. Respiration (left) generally vesicular, with moist râles extending almost to base; right, vesicular without râles. Heart normal, except systolic soufflé at pulmonic and aortic areas. Urine: color pale, slightly acid, specific gravity 1.009; no albumen.

January 30, 1891. Condition much improved. Weight 107 pounds. Little cough and no expectoration. Temperature about the normal.

February 1st. Gave .0003 of paratoloid; no reaction. 3d. Gave .0006; no reaction. 5th. Gave .001; no reaction. 6th. Weight 104 pounds. 7th. Gave .0015; no reaction. 10th. Gave .0025; reaction followed; temperature rose to 101°, with pain in the upper part of the chest and right arm. 12th. Gave .0025; no reaction. 14th. Gave .0035; no reaction. 17th. Gave .0045; temperature rose to 102° at 4 P. M., and then quickly fell off to normal. During the reaction there was considerable discomfort and pain in the chest and limbs. 19th. Gave .0045; no reaction. 20th. Weight 106½ pounds. 21st. Gave .0054; temperature rose to 100°. 24th. Gave .0054; no reaction. 26th. Gave .0066; no reaction; sputa for first time, one bacillus. 27th. Weight 107½ pounds. 28th. Gave .0078; no reaction.

March 3d. Gave .009; reaction; temperature rose from 96½° to 101° with much pain and tenderness in the diseased portion of the lungs. 5th. Gave .009; no reaction. 6th. Weight 104½ pounds. 7th. Gave .0102; no reaction. 10th. Gave .0114; a trace of reaction; temperature to 100.4°. 12th. Gave .012; no reaction. 13th. Weight 107 pounds. 14th. Gave .0132; a trace of reaction; temperature to 100°. 15th. General condition good, eats well, sleeps well, very little cough in the morning, none at other times. Weighs more than ever before. Chest: front, resonance right, good; left, dullness extends from apex to cardiac dullness; resonance in axilla. Respiration: right, normal; left, a little prolonged just below clavicle; elsewhere vesicular with a few râles as far as base. Back: resonance on the right, good; left, dull half down scapula; good below. Respiration; right, normal; left, vesicular with a few râles in region of dullness. Slight concentration of voice. Voice-sound at apices. 16th. Temperature down to 96°. 17th. Gave .0144; trace of reaction; temperature to 100°. 19th. Gave .0156; no reaction. 20th. Weight 107 pounds. 21st. Gave .0168; trace of reaction. 24th. Gave .018; no reaction. Sputa No. 0. Treatment given up as we could see no beneficial effect, and she thought it was doing no good. 31st. Has continued to do well, weight increased, fair strength, almost no cough, and no expectoration.

The sputa in this case, what little there was, came, judging from the cells, chiefly from the fauces and trachea. An examination of the sputa showed enormous numbers of bacilli chiefly in clumps.

CASE IV. A. F., December 13, 1890. Female, married. Family history negative. Came to America when thirteen years old, and since has never been

ill. Has had a cough for a year and a half, and for a year, a poor appetite. Is losing strength and has lost about 25 pounds. No hemorrhage. Night sweats during the last three months, very profuse during the last three weeks. During the last year catamenia have been regular but very scanty. Four weeks ago was in the City Hospital on account of some uterine trouble.

**Physical Examination.**—Weight 115 pounds; pulse 95; temperature 98.6°. Heart and abdomen normal. Lungs: right front, dullness as far as third rib, respiration feeble, broncho-vesicular with moist râles as far down as the edge of the fourth rib and a little lower after cough. Bronchophony over area of dullness; occasional dry râles. Left front: respiration rather harsh with moist clicking on expiration along edge of sternum, otherwise normal. Back: Dull over upper half right, and impaired over whole of left; respiration, upper half, right, harsh tending to bronchial; moist râles as far as angle of scapula, and some concentration of voice; below normal. Respiration on left, upper half bronchial, broncho-vesicular below, abundant moist râles throughout, increasing towards base and concentration of voice throughout.

Urine, acid; color normal; specific gravity 1.020; no albumen.

January 30, 1891. No change in chest. Weight 112½ pounds. Temperature running about normal.

February 1st. Gave .0003 of paratoid; no rise of temperature, but complained of pain in back and chest, and throat became a little sore. 3d. Gave .0006; same as before. 5th. Gave .001; no reaction; sputa No. 8. 6th. Sputa No. 7; weight 112½ pounds. 7th. Gave .0015; no reaction. 8th. Temperature rose at noon to 100°. 9th. Sputa No. 3. 10th. Gave .0025; no reaction; sputa No. 5. 12th. Gave .0035; no reaction; sputa No. 0, as found in two different trials, with two cover glasses each. Sputa is clearer, more glairy than at first, also increased, cough diminished. 13th. Sputa No. 8; weight 111 pounds; slight rise in temperature. 14th. Gave .0045; no reaction; sputa No. 4. 15th. Temperature rose to 101°; sputa No. 3. A number of small, red spots over chest and shoulders. 16th. Temperature rose same as yesterday; sputa No. 4. 17th. Gave .0055; followed by moderate rise of temperature; sputa No. 2; thick, yellow, but profuse. The nurse considers the patient stronger, but I cannot see any difference except in her spirits. 18th. Sputa No. 2; no elastic fibres. 19th. Gave .0055; no reaction; sputa No. 5. 20th. Weight 112½ pounds. 21st. Gave .0066; sharp rise of temperature to 102°, with general pain, occurred in the evening. 22d. Same reaction as yesterday. 24th. Gave .0066; slight reaction; sputa No. 5. 26th. Gave .0072; no reaction. 27th. Weight 112½ pounds. 28th. Gave .009; no reaction.

March 3d. Gave .0102; no distinct reaction. From this date on, the temperature became quite variable, rising to 102.5° or falling to 95.5° without any apparent cause. Sputa No. 6. 5th. Gave .0102; slight reaction. 7th. Gave .0102. A sharp drop to 96° followed by as rapid a rise of 5°. This associated with considerable discomfort and inability to take food. Looks badly. 9th. Appetite poor, general weakness, losing ambition, night sweats.

**Physical Examination.**—Front, dullness as before. Respiration: right upper third, harsh; expiration

bronchial, with moist râles, not abundant, over region of dullness and to the base. Left, normal; râles just above and below the clavicle. Back: left dullness as before. Respiration same. Râles on left over same area but not so abundant; right unchanged.

10th. Gave .01; no reaction. 14th. Gave .0114; a moderate reaction during the night, temperature rose to 102°. 17th. Gave .0114; no distinct reaction. 19th. Gave .0126; no distinct reaction; sputa No. 4. 21st. Gave .0126; no distinct reaction, but temperature rose to 102°. 24th. Gave .0138; no reaction; sputa No. 5. At this date treatment was stopped as we could see no benefit, and it was clear that patient's general state was by no means as good as when we began. Weight 111 pounds.

April 11th. Since last date temperature has returned to nearer the normal, the cough is more difficult and the strength distinctly better. Lungs: front, slight increase of pitch and sense of resistance over right apex, respiration feeble to third rib and diminished to fifth. Back: left, dull over whole with more râles than before. Otherwise no change from last record.

CASE V. M. D., October 10, 1890. Female, single, twenty-three years old. Family history negative. Has had pertussis, measles, scarlet fever and chicken-pox. As a young girl, never has been very strong, but has had no serious sickness. Present illness began last winter when she had the gripe. Since then has had a cough. Five weeks ago had two hemorrhages and lost considerable blood. Since June has lost nine pounds. During the last month cold night sweats two or three times a week. Catamenia scanty every five to six weeks. Almost constant headache, breath short especially after exercise, feet and hands swell, bowels regular, appetite poor, sleeps well.

**Physical Examination.**—Weight 111 pounds; pulse 80; temperature 98.4°. Lungs: dullness throughout right side front and back; good resonance on the left. Respiration, right front, vesicular, expiration harsh and prolonged, abundant moist râles with bronchophony at apex; left front normal. Right back: expiration in upper third, vesicular, elsewhere with scattered moist râles finer than in front, also bronchophony throughout; left back normal. Heart normal. Dullness over liver normal.

Urine high, acid; specific gravity 1.018.

October 25th. Examination of front of chest shows no change.

February 13th. Weight 109½ pounds. Left front normal; right, dullness throughout, marked at apex. Respiration bronchial in upper third, harsh below; an abundance of medium and fine moist râles throughout. Left back normal; right, dull throughout, with bronchial respiration and rather coarse, moist râles throughout. Temperature running from 97.5° to 101°; sputa No. 2. 14th. Gave .005 of paratoid, followed by diffuse pain in bones and left lung, but no rise of temperature. 17th. Gave .001, followed by same symptoms as before. 19th. Gave .002; sputa No. 2. 20th. At 4 A. M. temperature rose abruptly from 98° to 101.8°, the first definite reaction. 21st. Gave .003; same rise as before, but in the evening. Weight 110 pounds. 24th. Gave .003; temperature rose to 101.2° in the evening; sputa Nos. 3, 4. 26th. Gave .0042; sharp rise to 101° at night. 27th. Same rise to-day. Weight 107½ pounds. 28th. Gave .0042; temperature rose from normal to 103.5° at 9 P. M.

with considerable discomfort and pain in the chest. Sputa No. 2.

March 3d. Gave .0042. 5th. Gave .005; reaction followed. 7th. .005; no reaction followed. Treatment given up as patient was steadily going from bad to worse. 28th. Physical symptoms about the same, dulness and bronchophony more marked, and râles coarser in back than front. Sputa on the 24th. No. 3.

April 11th. General state distinctly worse, is clearly losing ground. Lungs the same, except that the right apex is resonant with a metallic click below clavicle.

CASE VI. L. M., February 4, 1891. Female, married, twenty-eight years old. Sister died of phthisis. Measles and pertussis when a child. Cough began last July. Weight, 87 pounds. Temperature, 98.5. Pulse 120. Respiration, 22.

February 13th. Weight, 89½ pounds, temperature showing evening rise to 101° or 102°. Lungs: front, resonance good on right; on left, dull in upper half with tympanic quality in places, fair elsewhere. Respiration: right, vesicular with a few scattered moist râles in upper fourth, normal below; left, bronchial, in places amphoric. Abundant moist râles half-way down chest. Bronchial voice and whisper marked in region of dulness. In lower third in sub-axillary region, flat and respiration absent. Back: resonance right side normal; left, dulness throughout, becoming flat towards base. A few râles in supra-spinous fossa right; left, respiration rather faint, abundance of coarse, moist râles throughout except at base where respiration is scarcely heard. Sputa No. 8. 14th. Gave .0005 of paratoloid at patient's request. No special rise of temperature or other symptom. 15th. Temperature rose sharply from 98.4° at 8 A. M., to 101.5° at 1 P. M., then fell off. No marked pains. Sputa No. 8. 16th. Same rise of temperature followed by a second rise in the evening. Sputa No. 2. 17th. Gave .001. Temperature rose to 103° in the evening, with much pain in the left side of the chest and limbs, sweating, face pinched, respiration rapid and shallow. Patient preferred to sit up, evidently had some orthopnea. An erythematous rash also appeared on the forearms. Sputa No. 3 with elastic fibres.

Temperature continued high from this date on for some weeks, rising from 98.1° in the morning to 103° or 104° at noon, then dropping to rise again in the evening; thus tracing a letter M. During this period she lost strength rapidly, and the outlook did not seem very bright. On the 20th, patient weighed 89 pounds. For some time the number of bacilli in the sputa remained small, No. 2 or 3, but later rose again to 7 and 8. The temperature chart closely resembles that given of the prolonged reaction in leprosy.

Examination of lungs March 1st, was as follows: front, right, resonance fair; left, dull. Respiration, right, normal; left, bronchial, in places amphoric, with moist râles throughout. Bronchophony on left side. Back: resonance dull in the upper half of left side and the right supra-spinous fossa, fair elsewhere; respiration, right, vesicular with moist râles in the supra-spinous fossa; left, vesicular, feeble with moist râles in the upper two thirds. After the prolonged reaction had passed off, patient picked up, gained strength, a pound and three-quarters in weight, and was discharged much relieved April 1, 1891. This refers to the state following the use of paratoloid, not that on entrance.

CASE VII. I. J. November 21, 1890. Female, single, forty-five years old. Father died of phthisis. Fourteen years ago had scarlet fever; four years ago, diphtheria. Caught cold in July. Has had two small hemorrhages and lost about twenty pounds, but the strength is still good. Weight, 80 pounds.

February 14th. Weight, 81 pounds. Pulse thin. Temperature rising to 100° or 101° at night. Lungs: front, resonance impaired at apices; below fair, but high pitched. Respiration: right, harsh and vesicular in upper third; normal below, without râles; left, inspiration vesicular; expiration bronchial in upper half; moist râles throughout. Back: resonance on left; dull throughout right; high pitched in supra-spinous fossa. Respiration: right, somewhat harsh; moist râles in the supra-spinous fossa; none below; left, generally vesicular, with moist râles throughout. In the left supra-spinous fossa marked bronchial whisper. Sputa No. 3. Gave .0005 of paratoloid; no reaction. 18th. Gave .001; reaction to 104° at 8 P. M. followed. Sputa No. 6.

From this time the high temperature occurred every afternoon; the appetite and strength failed rapidly; and besides the above it may be noted as common to all, that a certain amount of tenderness occurred at the point of injection; that during treatment the temperature rose higher than before or after, even when no "reactions" occurred; that after the first elation the appetite failed, and that no symptoms referable to the kidneys, other abdominal organs or nervous system occurred.

#### SUMMARY.

CASE I. Showed no improvement, such changes as occurred being only such as were to be expected from rest in bed and the appliances used. In the first part of treatment slight swelling occurred which may or may not have been due to the paratoloid.

CASE II. Showed no improvement. Strength and appetite were impaired. Sputa with bacilli returned, and the progressive gain in weight was arrested.

CASE III. Bore the drug better than the others, continued to gain slightly in weight; developed cough, expectoration, and finally enormous numbers of tubercle bacilli. No improvement occurred in the lungs.

CASE IV. Showed no improvement while under treatment, but lost strength. Since it was stopped the lungs have cleared up somewhat and the strength returned in part.

CASE V. Prompt and rapid failure which has continued.

CASE VI. Prompt and alarming increase in all the symptoms with slow recovery to former state.

CASE VII. Prompt and alarming increase in all the symptoms, no improvement, rapid decline.

CHINESE GYNECOLOGY. — A patient with prolapsed uterus lately consulted a Chinese doctor, when the learned man ordered a blister to the shaved crown of her head, in order to draw the prolapsed organ back again.

# SOME NOTEWORTHY CLINICAL FEATURES IN CASES OF MALIGNANT DISEASE: WITH REMARKS.<sup>1</sup>

BY HENRY W. BROUGHTON, M.D., JAMAICA PLAIN, BOSTON.

The two cases that I have the honor of presenting to your attention to-night I do not wish to report in detail. It is my purpose, rather, to sketch as briefly as possible their history, so that I may emphasize certain features that are of interest. They are both cases of cancer, the one of the rectum, and the other of the uterus. In some particulars, they stand in marked contrast. The first, the case of rectal disease, exhibiting that somewhat rare symptom, bulimia, or a morbid craving for food, and requiring but little morphine for the control of pain. The case of uterine cancer is, on the contrary, chiefly remarkable for the enormous amount of morphine given subcutaneously.

## CASE I. Cancer of Rectum, with bulimia.

On January 23, 1890, I was called to see a Miss L., a maiden lady, sixty-eight years of age. I learned from her and her friends the following history: Patient was born in Providence. Her family history showed that two paternal aunts and a number of first cousins on the father's side had died of cancer. Patient was a somewhat singular and crotchety person, although in her younger days she had been a beautiful and cultivated woman. She seems to have been utterly unaware that she was possessed of a remarkably vigorous appetite from early years. This she always indignantly denied, persisting that she really ate most sparingly. The menopause occurred at fifty-four, fourteen years ago. Seven years before my visit, she was seized with some acute dyspeptic attack, and was ill for four or five months. The direct cause seems to have been over-eating. She made a slow and tedious recovery. Her attending physician at the time suspected cancer of stomach. She was henceforth comparatively well until one and one-half years before my visit, when she began to complain of "bleeding piles, and diarrhoea," accompanied by a failure of "strength and appetite," as she alleged. This latter point was derisively denied by her most intimate friend, who averred that she ate more than ever. She was next seen by Dr. Sarah Crawford, of Roxbury, who reports that she found several excrescences about the anus that were exquisitely painful, with considerable induration. The disease was pronounced cancer. Dr. George W. Gay saw her a little later, and advised against operative interference, considering the condition hopeless.

At the time of my visit I found her bedridden, with a marked cachexia. She was a slight, wasted, nervous woman; and a large mass of cancerous tissue was found surrounding the anus. The growth was markedly indurated, apparently scirrhus. Anus would just admit a probe and nothing more. Hard and enlarged glands were felt in left inguinal region, through abdominal wall. Uterus not examined. The disease was now of a year and a half duration, but had rapidly advanced in the past four months. Cervical glands had also begun at the same time to enlarge, and there was a circular perforating ulcer through velum palati, which had first appeared as a small hard tumor. There was a constant discharge from anus, resembling gum arabic, with but slight odor. There was frequent large escape of flatus. At the time of visit there had been no natural defecation for three weeks. The patient

complained of constant pain, but had refused all opiates. She said that she had no appetite, and really ate little or nothing.

I learned from her friend the following additional facts. From her early years she has had, to quote the exact words, a "*voracious appetite*." The heartiest and richest food was usually taken with avidity. She has naturally had frequent digestive disturbances. After her menopause at fifty-four she had severe hemorrhage from uterus and also from nose, and her desire for food became more conspicuous, of which fact she never seemed aware. She ate heartily three times a day of rich and greasy meats, game, gravies, salads, with elaborate desserts. The more indigestible articles, like ham, bacon, shredded beef, pickled fish, steak, clams, lobster, ices, chicken, vegetables, coconut, etc., were taken without difficulty.

After the development of the cancer in July, 1888, there was not the slightest change in this idiosyncrasy. Although failing in health, her unnatural appetite continued. At the time of my first and only visit, after the cancer had existed for a year and a half, and although weak, wasted and bedridden, she still had her three meals a day, and relished them, too. As the disease encroached upon the calibre of the bowel, and as the anus closed, attacks of vomiting were very frequent, consisting of large quantities of undigested food. At intervals of days or even weeks, scybalous masses would somehow find their way through an opening that would ordinarily admit no more than a probe. She was much changed mentally, and was irascible, and suspicious of her best friends. She resolutely refused all opium for her pain. It seemed to those about her as if her suffering was more mental than physical.

As has been stated, I only saw the patient once. She suffered much of many physicians. She ended her days under the care of a homœopathic practitioner. For a few data of her career subsequent to my visit, I am indebted to her intimate friend, a most intelligent lay observer. She lived six months longer, dying on July 16, 1890, the cancer having thus existed for two years. Her remarkable appetite continued until ten days before death. When reminded that she ate unusually she would fly into a passion. She ate constantly. Her breakfast would consist of ham, bacon or steak, with two or three cups of coffee and several rolls. For dinner, the richest of fish, game or meats, with hearty desserts; and for supper, cold ham or bacon (of which she was especially fond), cold meats or chicken, and orange sherbet. The vomiting gradually increased, but made no difference with appetite. The discharge from rectum continued like a sticky, gummy solution of slight odor, occasionally streaked with a brick-dust deposit. This was constant, and often amounted to a gallon a day. Now and then scybalous masses were passed, the patient always assuming the standing posture for this performance. On one occasion figs that had been eaten eight weeks before were passed per rectum. The disease in the fauces evidently kept pace with that of the rectum; for in attempting to swallow, regurgitation of fluid through the nose and left ear was a frequent occurrence. She began a few months before death to take a little morphine by mouth, and later subcutaneously, although in small doses. At length food began to cause more distress, and she grew rapidly weaker. Finally she could eat no longer, vomiting was so constant; and in ten days she died. There was no autopsy.

<sup>1</sup> Read by invitation before the Obstetrical Society of Boston, February 11, 1891.

CASE II. Cancer of Uterus, with excessive use of morphine.

Mrs. D., American, sixty-two, widow, brunette. Father died of paralysis at fifty-nine; mother of apoplexy at eighty. A twin sister died in childhood of scarlet fever. Patient was never very well until after the appearance of the catamenia, at eleven years, when she improved in health. She was married at twenty-two, and had four miscarriages and five children, with tedious convalescence. Menopause at fifty-two, ten years ago. Eczema of hands and feet soon developed, which was persistent until the appearance of the cancer, when it subsided. Nearly four years ago she began to have attacks of sharp hæmorrhage from the uterus, accompanied by "unwell pains." This was in 1887, six years after menopause. The pain soon became more or less constant.

In April, 1887, I learned of this history, and suspecting serious disease made an examination. I found a number of nodules upon the cervix, with some induration. A piece was excised, and submitted to Dr. Gannett for examination, who found no evidence of cancer. Dr. Homans then saw her with me. He agreed that the disease was probably malignant. He advised removal to the Massachusetts General Hospital, where she went in December, 1887. He then curetted cervix and applied the actual cautery. She was in the hospital six weeks. Shortly after her return she began, early in 1888, to take by the mouth, for pain, liq. morphia sulphatis, in quarter-grain doses. In a few weeks she increased to half a grain, which she took in pill. In two or three months she was taking two or three grains at a dose, by mouth.

The patient was a calm and courageous woman, not of hysterical temperament. She always resisted the idea of morphine until the very last, and the almost unprecedented increase about to be described was taken, not so much as a matter of habit, as for the intense pain. Her family were compelled to use every persuasion and even to resort to subterfuge to induce her to take a sufficient amount.

In 1889, she began to use the hypodermic syringe, requiring at the very outset two or three grains of morphine for each injection. This amount only gave moderate and temporary relief. I now only saw her at long intervals, as some emergency arose. In December, 1889, cachexia was very evident. She was emaciated and much troubled with constipation and difficult micturition. A constant uterine flow was present; it was dark brown, sometimes dirty white. There was an occasional slight hæmorrhage, but nothing severe. Advancing disease had fused the uterus and surrounding tissues into a solid mass, filling the pelvic cavity and easily felt through the abdominal wall. She suffered greatly although taking morphine constantly.

During 1890, the disease made mournful and rapid headway. On June 16th, I called upon her, not having seen her for several months. I was asked by her son-in-law to give the usual subcutaneous injection which was then due. I, of course, assented, and asked what dose was required. At the last account she had been taking some two or three grains at a dose. Imagine my surprise when he told me that it would require thirty grains to give any ease at all. He assured me that this dose had been frequently given, and that it had been repeated every three or four hours; thus 120 grains had been taken daily under the skin. This sort of thing had been going on for a month. I there-

fore injected this amount. He had been wont to dissolve the thirty grains in two drachms of boiling water, and then to introduce the whole quantity while very hot by four different punctures. This would sometimes not put her to sleep at all, but would simply make her comfortable. Again, she would drop into a natural sleep for a few hours. Pupils and pulse were unaffected. There was frequent nausea. The numerous punctures caused no disturbance. In addition to this enormous amount of morphine she was also taking large quantities of antipyrine or phenacetine, which she preferred, also chloral, and bromidia in form of bromidia. The phenacetine was used in ten-grain doses, especially at night, an ounce bottle only lasting three or four days. Her failure was now more rapid, but none too fast, for her distress was great. She at this time began the inhalation of ether, which was a valuable addition. She inhaled a pound, and later a pound and a half a day, for four months. She continued the morphine in about twenty-five-grain doses. The ether enabled her to diminish the amount to this point. Phenacetine and bromidia continued as before.

On Thursday, the 16th of October, 1890, while in the bath-room, she was heard to shriek loudly, and was found in an epileptiform convulsion, which lasted five minutes. The urine had been diminishing in amount for some time. Dr. Parsons of West Roxbury, who lived near by, was called on from time to time in my absence, and was with her during the last few days. A second convulsion occurred on the next day (Friday), more severe; and a third on Saturday. On Sunday she had several convulsions, and died of uræmic poisoning on Monday, October 20, 1890, after nearly four years of suffering.

Autopsy by Dr. Whitney, forty-eight hours after death:

"The changes were greatly obscured by the corrosive action of the undertaker's injection (which was unfortunately made). It was seen, however, that the greater part of the uterus had been destroyed by a new growth that was sloughing. In the broad ligament on both sides were numerous abscesses, one as large as an orange, which had dissected up some way into the iliac fossa. The ureters were dilated, as were the pelvis and calices of the kidneys, the substance of which was atrophied and rendered dense. In the right kidney was a small nodule of new growth. No other nodules were detected. The diagnosis is cancer of the uterus, with purulent parametritis; secondary growth in the kidney, hydronephrosis."

By reviewing this history of Case II, it will be seen that morphine was used continuously for nearly three years in rapidly increasing doses. The hypodermic syringe was in constant use for the last year and a half. For eight months the patient received subcutaneous injections of from 20 to 30 grains for each dose, making a daily total of from 80 to 120 grains under the skin. This was without symptoms of poisoning or without more than a partial relief of suffering. Antipyrine and phenacetine, chloral hydrate and potassium bromide, were used for about three years in large quantities. Ether, from a pound to a pound and a half a day, was inhaled for about four months in addition to the continuous use of morphine and the other medicines.

In some particulars this history is very unusual. I have thus far been unable, in a moderately careful

search at the library, to find anything recorded that equals it. There is, however, "nothing new under the sun," and very likely a more prolonged hunt would bring something similar to light. Dr. Hinckley, in the *New York Medical Journal*, March 29, 1884, reports a remarkable case where a woman, a morphine habitue, took 85 grains (in divided doses) of sulphate of morphia subcutaneously daily for nine days. He adds, as his belief, "that this records the largest quantity of morphine taken by any living being within twenty-four hours." The rumor of an astonishing case, unpublished as yet, and which surpasses mine came to my ears the other day, which I finally traced to my friend, Dr. W. D. Hodges. He has kindly consented to read it to-night.

In conclusion, it may be of interest to add the following: The "Britannica" is authority for the statement that, "among opium eaters in India," the amount consumed ranges from "four to forty-six grains of opium a day, the average being five to seven grains." Reese's "Toxicology" states that, "thirty, fifty and even one hundred grains of opium a day are taken by some opium-eaters. De Quincey, the English opium-eater, brought himself to drink nine ounces of laudanum, equivalent to 333 grains of solid opium, a day." Wood's "Therapeutics" makes one grain of opium equivalent to one-quarter of a grain of sulphate of morphia. Therefore, the 120 grains of morphia given to my patient are equal to 480 grains of opium, which is larger than De Quincey's dose.

#### REPORT OF 1168 CASES OF LABOR IN PRIVATE PRACTICE.<sup>1</sup>

BY WILLIAM A. DUNN, M.D. (HARY., 1875).

In June, 1884, I had the honor of reading before this Society the statistics of 550 cases of midwifery I had attended. I present this evening the records of 1168 obstetric cases with which I have been connected since October, 1875. During the past two years I have attended only 22 cases as I had determined to accept only those obstetric patients whom I could not easily refuse.

Of the first 550 patients, I attended 48 during the thirteen months I was associated with Dr. John G. Blake. Of the last 618 cases, 136 were attended by physicians who were associated with me from time to time. Many of these patients I saw in connection with these gentlemen; to several others I was called to assist. Six hundred and thirty cases were primiparæ. One patient I delivered eight times, one patient six, several five and less. At least two-thirds of the cases presented with the occiput anteriorly. There were 47 presentations of the occiput posteriorly. These latter cases caused me more anxiety and trouble than almost all of the other presentations combined. Fifty-three patients were delivered before my arrival. In all but three I delivered the placenta. Seven hundred and eight cases were normal and could have been attended by a midwife who might not have been meddling.

In only two cases was there post-partum hemorrhage which demanded protracted treatment and much anxiety on my part immediately after delivery. In one case there was a severe post-partum hemorrhage on the

ninth day, during which the woman at one time was apparently dead. Dr. Jarvis, of the West End, afforded me invaluable assistance in this case, which recovered. There was only one case of ante-partum hemorrhage.

There were 45 simple miscarriages, all of which made a good recovery. Having satisfied myself that the womb had been emptied, and having given ergot, these cases did not receive more than the ordinary obstetric care. In no case did I consider it necessary to use the curette, twelve miscarriages gave me trouble with the placenta, which I removed piecemeal in every case of this character. I followed up the operation with intra-uterine antiseptic injections with good results.

There were three induced instrumental abortions to which I was called when septicæmic symptoms occurred. These cases I at once sent to the hospital, where they died. There were fifteen premature deliveries, one premature delivery induced at the eighth month on account of excessive vomiting, and eight cases of edema of the feet and hands with albuminuria.

I have had three cases of puerperal convulsions in my own practice. I sent these cases to the Lying-in Hospital, as they could not receive proper treatment at their homes. I assisted Dr. W. L. Richardson in a noted case of puerperal convulsions while I was surgical house pupil at the Massachusetts General Hospital. In five cases the fœtus was macerated. Of these patients one died; one case, the mother of eleven children, recovered from convulsions immediately after forced delivery; the urine was loaded with albumen. The smallest fetus weighed less than three pounds, one weighed six and one-quarter pounds. Both of these children are alive to-day, well-formed, healthy and as well developed as children of their age.

I performed version in 62 cases, either for posterior occipital positions or for abnormal presentations of the arm, shoulder or trunk. In two cases the fœtus, which was at full term, died from uncontrollable hæmorrhage of the lingual artery.

In both of these cases, the after-coming head was arrested, and resisted all efforts to induce expulsion by making pressure on the bones of the face. It was necessary to apply as much pressure as possible on the lower maxilla with the result above stated. I consider it a dangerous practice to yield to the temptation to make traction on the lower jaw by placing the finger in the mouth. I believe, however, that the practice is not uncommon. In one case of twins the head of the first fetus presented normally. The arm of the second child presented. Version was performed in this delivery.

I have always endeavored to prevent rupture of the perineum. I have had but one case in which there was a rupture through the recto-vaginal wall. The patient had a narrow pelvis; the position of the head was posterior; application of the forceps failed; version was successful. The patient refused to take ether. The child had a massive head. I could not obtain assistance in this case; and moreover, I was obliged to deliver the woman in a room in which the bed occupied almost all of the space. While applying the forceps I was obliged to stand in the bed, at its foot, in order to obtain room for the free action of my arms. The woman and child lived. The mother afterwards developed Bright's disease of the kidneys, and became too weak to endure an operation. She died three and one-half months after confinement.

<sup>1</sup> Read, by invitation, before the Obstetrical Society of Boston, February 14, 1891.

The oldest primipara was forty-two and one-half years. She was delivered of a large, healthy child with the assistance of the forceps. The youngest patient of whose pregnancy I was aware, was fourteen years of age. I advised her removal to the Carney Hospital, where she was delivered. I very decidedly agree with Dr. T. A. Reamy, of Cincinnati, that early rupture of the membranes and attempt at forcible dilatation of the cervix by the finger or fingers of the accoucher or midwife, and the improper use of ergot, are far more fruitful sources of laceration of the cervix than the obstetric forceps.

There were three cases of pelvic cellulitis, and one case of deep and extensive pelvic abscess, on which I operated with success. This woman had borne twelve children.

There was one case of emphysema of the neck, face and chest following labor. I reported this case in the *Boston Medical and Surgical Journal*.

Four cases of placenta previa all of which recovered.

One case of hydatiform mole with very profuse hemorrhage. This case was reported in the *Boston Medical and Surgical Journal*.

One case of convulsions at seven months. I immediately applied ether, performed version, and was rewarded by a living child and by the recovery of the mother. Forcible and rapid dilatation of the os was performed in this case.

Fifteen cases of breech presentations. After one delivery there was a very severe post-partum hemorrhage. I have had very little difficulty with breech presentations.

One case which I investigated as exhaustively as possible did not menstruate for fifteen months previous to her confinement. I remember with much exactness that I was engaged to attend this patient nine months after her last menstruation. It was at the end of the fifteenth month before she sent for me. This case may be relegated to the pages of fable, but at the time there was much realism for me in its conditions.

One fetus presented with the cord twisted four times around the neck.

There were four cases of prolapsus of the funis. The fetus died in each case.

An unusually trying and difficult case was the following: The labor had lasted eight hours, and the anterior lip was so edematous that it protruded at the vaginal orifice; application of the forceps was deemed inadmissible; the edematous lip was punctured in several places without avail. Version was finally performed, and the mother and child progressed satisfactorily. I have always endeavored to give the benefit of the doubt of life to the fetus, whose coming had been attended with unusual difficulty. In a large number of cases I was rewarded by my efforts for resuscitation by the recovery of the child. In the face of many difficulties I worked in one case one hour and ten minutes and finally I saw the child continue to breathe. In another case forty minutes and in another thirty minutes with similarly good results. I have had two deaths from septicemia. In one of these cases, where delivery was instrumental, the patient insisted on an anæsthetic on the fifth day to attend to her child. Peritonitis ensued, death occurring on the twelfth day.

In another case of septicemia, the patient had a normal delivery. I advised injections for constipation. A fellow tenant loaned Mrs. C., her syringe,

which formerly had been used on an obstetric patient. A chill declared itself on the next day, and marked septicæmic symptoms appeared. Finally, the patient died.

Two cases of death from shock immediately after labor.

One of these patients had a narrow pelvis, and always presented an abnormal labor. She was the mother of ten children, who came into the world either by breech, arm or other abnormal presentation. I attended her three times previously — for a breech, an arm, and on the third time for prolapsus of the funis and arm. Ether was refused. I was not able to replace the funis. The baby died before delivery, and ten minutes after the expulsion of the after-birth a very severe post-partum hemorrhage occurred, which was followed by death.

Mrs. L. was a delicate, small woman, who was delivered of a large child. Immediately after delivery the woman expired, presumably from heart-failure or nervous shock.

There was one case of difficult labor, with occipital posterior position, which gave me a great deal of trouble and apprehension on account of a rigid os which resisted every effort for dilatation. I gave three doses of chloral, of fifteen grains each, which were administered at intervals of an hour and a half, with fairly good effect. The os, after eighteen hours, was only as large as a half-dollar, although the pains were continuous and very distressing. Dr. Schram, my then assistant, attended the case with me. We determined to allow the patient a respite from examinations for two hours. In our absence the semi-drunken husband of the woman gave her the remainder of the chloral, containing sixty grains. After instrumental delivery, the patient, who was almost comatose, sank back and died. The baby lived.

I have had two cases of hydramnios. The last case which I delivered was of this character. The patient presented the external indications of a multiple pregnancy. A very large amount of fluid preceded the birth of a very small fetus.

One case of hysteria, which ceased after delivery by forceps.

I have applied the forceps in 169 cases when the usual necessity presented, namely: inertia, non-rotation, no progress, cessation of the pains, exhaustion, and dead fetus, arrest of the head, or when the vagina had become hot and dry after a tedious labor.

As I have before stated, I have had only one case in which the rupture of the perineum extended through the recto-vaginal wall. In this case the bedroom was not much larger than a bath-room in an ordinary dwelling.

In only one case was I brought into the presence of those conditions which seemed to demand craniotomy. A deformed woman with narrow pelvis sent for me for her third labor. I attended her during her previous accouchements. The first time the fetus presented with prolapsed funis. Her second labor was tedious, but not particularly difficult. In the third labor, which lasted thirty-four hours, the presentation was the right occipital posterior position. After the usual delay I called an eminent consultant, who advised craniotomy. I afterwards succeeded in obtaining the valuable assistance of Dr. W. L. Richardson, for whom I had sent at first, but he was then unable to come. Dr. Richardson agreed with me, that it would be worth while

to attempt version, which was successfully performed. The child did not breathe regularly for forty minutes after birth. A remarkable incident in this case was the complete absence of the rectum in the child. Dr. J. C. Warren operated for an artificial anus. The baby lived fifteen days.

In the first fifteen days of June, 1884, I attended seventeen labors. The largest number of midwifery cases which came to me in twenty-four hours was five, (three of which I attended, my assistant attended one, and the other chose another physician).

Only a short time has elapsed since the discussions concerning the necessity and advisability of using vaginal antiseptic injections after labor were very frequent. In 1168 cases of labor I have never used the vaginal or intra-uterine injections unless special symptoms demanded them, or unless after instrumental labors, or when introduction of the hand into the uterus was necessary. I have never deemed it advisable to use injections after the routine suggested by some obstetricians.

I have always tried to look upon the obstetric condition from as nearly a physiological standpoint as possible. Fortunately for my peace of mind, I have educated my sensibilities to this standard of reflection. However, with some trepidation I frequently find my mind dwelling on the barrenness of the conditions which attended many of the cases to which I was called; and I am obliged to ask myself whether these patients did not progress just as well as if the careful nurse attended, and as if the convalescence continued three or four weeks instead of the hasty nine days, or in the large majority of cases two weeks; or whether a tender Providence compensated these patients in other ways for their lack of the luxury, assiduous care and constant nursing of their more fortunate sisters.

At least three-fifths of the patients I saw received unskilled attention from members of their own families, or from would-be sympathetic neighbors. If a nurse were engaged, she very frequently displayed the disturbances of heredity transmitted with seldom-failing constancy by the notorious Sarah Gamp.

I crave the indulgence of the Society for the unfinished manner in which these cases have been presented. It was my intention to have offered them in a more carefully tabulated form and with carefully arranged statistics. In fact, I consider this paper a mere abbreviation of the one which I intended to have prepared and to have read this evening.

#### THE OPERATIVE TREATMENT OF RECTAL CANCER, WITH ESPECIAL REFERENCE TO KRASKE'S SACRAL METHOD.<sup>1</sup>

BY PAUL THORNDIKE, M.D.

FAGET in 1739 performed an operation for the extirpation of the cancerous rectum, but the procedure found no favor in the eyes of surgeons at that time and it was not until Lisfranc devised a similar operation and described it in a paper before the French Academy of Medicine, in 1830, that any interest in the subject was displayed. The Lisfranc operation was excision (or resection) of the bowel from below, and all of the more modern operations are modifications of it. For the last seventy years this operation

of resecting the rectum from below has been asserting its claims, and to-day it is a procedure of unquestioned value in a considerable percentage of cases of cancer of the rectum. It is an ambitious operation, for its aim is a radical cure, by totally removing all diseased tissue. That this is possible is proven by the fact that there are on record dozens of cases reported by such surgeons as Koenig, Volkmann, Cripps, Allingham and Bardenhauer, which have been watched carefully for periods varying from three to ten years, and in which the disease never recurred.

I have found twenty-eight cases reported since 1885, which had been watched for periods varying from three to six and one-half years, in which the disease never reappeared. There are several recorded cases in which the cancer had been known to exist for between three and four years *prior* to operation, and in them no recurrence ever took place. So cures are certainly possible.

In studying the history of this operation we find that previous to Volkmann's work the mortality was very high (well over fifty per cent.) but that during the last few years, it has been steadily diminishing until now it is about sixteen per cent.

Among the best summaries of cases treated by this operation are those of

Billroth, who reports 698 cases, with a mortality of 23%	
Gross, " 193 " " "	20
Cripps, " 76 " " "	17
Ball, " 175 " " "	16½
Kelsey, " 140 " " "	15.7
Average mortality, 18.4%	

The individual experiences of surgeons with this operation vary a good deal, and among the best sets of cases reported are those of

Billroth, who operated on 45 cases, with a mortality of 42.2%	
Koenig, " (six years, 1884-90) " " "	16
Bergmann, " on 46 cases, " " "	11.3
Cripps, " on 39 " " " "	7
Czerny, " on 25 " " " "	4
Average mortality . . . . . 16.1%	
Average mortality, without Billroth, 9.6	

The great diminution in the danger of the operation has been brought about in two ways:

(1) As the experience of surgeons with the operation has become greater, they have learned to select their cases more and more carefully, and to draw a sharp line between the cases where the disease is situated high up and those where it is near the sphincters and easily within reach. Indiscriminate use of this operation is no longer the rule.

(2) The technique of the operation has improved vastly.

As to the permanency of the results attained with this operation:

Czerny reports 25 cases, with no return in 24% in 2 years.	
Koenig " 60 " " " "	10 " 3 "
Kuster " 65 " " " "	9 " 3 "
Billroth " 100 " " " "	17 " "
Cripps " 28 " " " "	10.7 " 3 "
Kelsey " 100 " " " "	6 " 10 "

These cases of Cripps and Kelsey are most faithfully reported, and the per cent. of cures is probably greater than the figures show in both cases, for of Cripps's twenty-eight cases, only fifty per cent. were known to have recurred, and of the other fourteen cases only three were reported cured although several others had been watched for nearly three years without recurrence.

<sup>1</sup> Read before the Surgical Section of the Suffolk District Medical Society, February 1, 1891.

In the same way with Kelsey's one hundred cases, only six are reported cured, they having been watched for ten years, but there were twenty-four others which were alive and well at periods from one to six years after operation. So that taking three years as a standard of time (and recurrence after this period has elapsed is very rare) there are cured at least ten per cent. of all cases which recover from the operation, and Mr. Cripps believes that this percentage is much nearer fifteen than ten.

As regards the amount of continence of feces after the operation, it is found that destruction of both internal and external sphincters means incontinence, but if a part of the external sphincter be preserved, although there is a temporary incontinence, more or less power over the sphincter is gradually regained. Of thirty-six cases reported by Cripps, twenty-three had complete continence, and six more partial continence, so in only nineteen per cent. was there incontinence. To sum up then :

(1) Excision of rectum from below is an operation with a mortality at present of about sixteen per cent., and rapidly diminishing as the cases are more carefully selected.

(2) If the cases are so selected the operation offers fair prospects for a cure, the present cures being at the very least ten per cent. of the cases which survive the operation.

(3) To insure these results the operation should be done only in those cases where the examining finger in the rectum easily reaches the upper limit of the disease. That is to say, a sharp line should be drawn between cases high up and cases easily within reach. The former are *inoperable* by this method. The latter are operable and comprise about twenty per cent. of all cases of cancer of the rectum.

*Colotomy.*—For the original idea of our operation of colotomy we are indebted to Littre, but the lumbar operation was described by Callisen in 1813, and with greater anatomical exactness by Amussat. In England it has found its strongest advocates, and even to-day among the more conservative men it continues to be the operation for the relief of rectal cancer. Since the experience with the radical operation has been taking a somewhat definite form, colotomy has been losing ground in surgical opinion, until now it is an operation of well recognized limitations. Mr. Bryant, than whom no man has had a larger or more varied experience, remains its strongest advocate, and his ideas with regard to it are about as follows :

He recognizes the fact that colotomy as a measure for the relief of cancer of the rectum is purely a palliative operation and prolongs life only by the alleviation of distressing symptoms. He also says that he approves of the radical operation in cases where the disease is localized and within reach, and the patient's condition favorable for operation. But he says that at the time when cases consult a surgeon for relief, they have already passed this period favorable for radical operation, and on this account he rarely has a chance of doing a resection or amputation.

At the International Medical Congress held at Copenhagen, in 1881, he presented a paper on the subject and reported a large series of cases. He reported one hundred and seventy cases with a mortality of forty-five, or twenty-six and one-half per cent., but insisted upon the fact that the operation suffered greatly in the hands of many surgeons as it is performed indis-

criminately and too late; and that the operation should be done before urgent symptoms of obstruction appear. To support his views he shows a series of thirty four cases where the operation was performed early, in which there was no mortality from the operation, while of one hundred urgent cases forty-five died inside of one month.

Cripps operates early and reports a series of forty cases (selected) with a mortality of only one case, or two and one-half per cent.

With regard to the prolongation of life by colotomy, Mr. Jessop, of Leeds, reports a most admirable series of cases: Of eighty-six cases of rectal cancer, fifty-two were allowed to progress without operation, while upon the other thirty-four colotomy was performed. Of the fifty-two without operation, the average duration of life was seventeen months, and in the cases operated on it was twenty-two and one-half months, showing that in these cases, life was prolonged on an average about six months by the operation.

Colotomy, then, is to be regarded as a palliative operation with a mortality so small as to be disregarded, and which should be done in cases where a radical operation is contraindicated. It offers to the patient relief from suffering, a retardation in the progress of the disease and a corresponding prolongation of life, for at least six months, and for a longer period if the cases can be operated on early enough.

The question of lumbar *versus* inguinal colotomy, cannot be discussed in a paper of this length. The surgical opinion of to-day seems to favor the latter operation, which is in use in most of the large European and American clinics; but it should be remembered in studying the results of the two methods, that the older operation is encumbered with a vast mass of old statistics which are of very little value to us to-day; and when comparisons are made they should be made upon a basis of the results accomplished during the last few years with both operations. If this is done, the results of the two methods will be found to compare very closely.

There remains for consideration a third class of operations, newer and more radical.

In 1885, Prof. Kraske described an operation for extirpating the cancerous rectum, which differs completely from the method of Lisfranc or any of its modifications. His idea was, that if he could devise a method of operating which would give him a better view of the structures upon which he was operating, and more space in which to work, he could greatly increase the number of cases which could properly be called operable.

In other words, his aim was to devise an operation which would accomplish a more complete extirpation without a corresponding increase in the mortality of the operation. After carrying out his ideas by a long series of dissections on the cadaver, he operated twice on the living, and published the results of his work soon after.<sup>2</sup>

Kraske's operation, or the sacral method as it is called, differs from the former methods of operating in the fact that the approach to the diseased part is effected from behind instead of from below. This is rendered possible by the enucleation of the coccyx and the removal of a small part of the left lower portion of the sacrum.

<sup>2</sup> Verhandlungen des xiv. Chirurgen Congresses und Langenbeck's Archiv, Band 33.

The details of the operation are briefly as follows: The patient is placed on the right side and an incision made in the median line from about middle of sacrum nearly to the anus. The soft parts to the left of the cut are then dissected up as far as the left margin of the sacrum and the coccyx is enucleated. Then the greater and lesser sacro-sciatic ligaments are divided on the left side, and there remains only to remove a little of the left lower part of the sacrum. This is done with mallet and chisel, taking away that part of bone which surrounds the fourth foramen on the left side: and completes the first stage of the operation.

[HOCHENEGG.]

FIG. 1. Showing the amount of bone removed by different operations. AB = Kraske, AC = Hochenegg. AD = Kraske, for extreme cases.

[HOCHENEGG.]

FIG. 2. Showing extent of incision and amount of bone removed. Resection partly done, and lower end of bowel brought out through wound.

The result is a large opening which gives an excellent view of the rectum within and affords ample opportunity to work without being cramped for space. No structures of great anatomical importance have been sacrificed, as the destruction of the fourth and fifth posterior sacral nerves results in no paralysis (motor or sensory) either of the rectum and bladder or of the muscles which the nerves supply. Indeed,

it is quite possible to go still higher and remove the bone about the third foramen without doing any permanent harm. Prof. Schede did this in one of his earlier operations with no further bad result than a slight paresis of the bladder wall which disappeared very shortly after. This part of the operation is easily performed, and the loss of blood is very slight and far less than by the older methods of operating.

The second part of the operation has to do with the removal of the diseased bowel. If the anal portion is not involved and the disease does not extend so high as to necessitate the wounding of the peritoneum, this is a simple matter.

A plug of gauze having been placed in the anal portion, the bowel is gradually freed from its attachments on the two sides and then from the prostate and bladder (or from the vagina) in front. The bowel should be completely freed before it is resected. An elastic ligature is then passed around the bowel and tied well above the upper limit of the disease, and then the bowel is cut across first below and then above the cancerous mass. In this way the wound is kept perfectly clean during the resection.

If the anal portion as well, is involved, it must be removed as in the Lisfranc operation, making the oval incision about the anus, and dissecting the bowel up from below. If the disease has extended so high that the peritoneum must be wounded in order to get at the upper limits of the disease, the resection is done exactly as described above, and when the bowel has been freed up to its peritoneal attachments, the latter are divided with scissors close to the rectal wall on each side. The bowel is then pulled down as far as may be necessary and then the parietal and visceral layers of peritoneum are brought together on each side by fine buried sutures of catgut.

It now remains to complete the operation in such a way as to leave for the bowel as serviceable an outlet as possible.

(1) If the anal portion has not been removed and we have done a simple *resection*, the two ends of the bowel are brought together and stitched all around or the two ends are joined in front and a posterior opening is left temporarily to be closed by a secondary operation.

(2) If the anal portion as well has been removed, there remains only to make an artificial anus in one way or another.

In the first place, then, if our operation has been a simple resection, the ideal way of closing the ends would be to sew them completely together all around the circumference of the bowel, but experience with the earlier cases has shown that even if there has been no tension on the sutures, they often tear out as a result of the peristaltic movements of the bowel and the passage of feces by the stitches.

Of Prof. Kraske's first eight cases where the operation was completed in this way, five died as a result of the tearing out of the sutures. So in many German clinics it is deemed best to leave a posterior anus for a time and then to close this at a second operation. Prof. Schede performs a preliminary colotomy on his cases so as to empty the bowel thoroughly from above before operating. Dr. Julius Hochenegg, first assistant in Prof. Albert's clinic in Vienna, in an article published in February, 1890, reported a case where he had completed a resection by telescoping the upper segment of bowel through the lower, and then putting

in a double row of sutures, one row above the anus and a second row around the margin of the anus. He claims that this is the best method of all.

Now as to the completion of the operation in cases where the anal portion of the bowel has been removed: In this case, after the diseased part has been dissected out, the end of healthy bowel is brought out through the sacral wound and stitched there, making a sacral anus and leaving the lower wound (anal) to heal with a drainage-tube packed into it. (See Fig. 3.)

[HOCHENEGG.]  
FIG. III. Showing sacral anus and anal wound, with drainage-tube packed into it.

The sacral anus in these cases is provided with a pad made by Leiter in Vienna. The pad does its work admirably and the patients are very comfortable while wearing it. (See Fig. 4.)

[HOCHENEGG.]  
FIG. IV. Showing method of applying pad to sacral anus.

In an admirable series of articles published in the *Wiener Klinische Wochenschrift* for 1889, Dr. Hoehenegg describes the whole history and detail of the operation, and reports thirty-nine cases, comprising all that had been done up to that time. Of these thirty-nine cases, eight died, a mortality of twenty and one-half per cent attributable directly to the operation. I have found recorded fifty-eight cases with nine deaths, a mortality of fifteen and one-half per cent.; a

mortality which is quite as low as the most favorable statistics show for the older operation.

	Cases.	Deaths.
Routier . . . . .	1	0
Kuster . . . . .	9	2
Czerny . . . . .	18	4
Moulinquet . . . . .	1	1
Boeckel . . . . .	3	0
Gerster . . . . .	1	0
Albert . . . . .	25	2 (to 1889)
Totals, 58	9	

In a letter dated January 17, 1891, Dr. Hoehenegg writes me of thirty later cases not yet published, so that the operation in Prof. Albert's clinic up to date numbers fifty-five with six deaths. Adding them to the list we get eighty-eight cases with thirteen deaths, a mortality of 14.7 per cent.

Various methods similar in many respects to that of Professor Kraske have been suggested and among others that of Dr. Levy of Berlin. He advocates getting at the bowel from behind, by temporarily enucleating the coccyx and turning it back in the skin flap and then replacing it after the resection is completed. He says the rectum can be readily reached up to the sigmoid flexure by this operation, and adds that if it is found necessary to remove a part of the sacrum as well in order to remove the growth, this can readily be done.

The Kraske operation then, would seem to be indicated in all operable cases of rectal cancer except epitheliomata of the anus and those cases where the disease exists as a well-localized mass readily removed by excision from below.

The latter operation is certainly less severe and should probably be done in cases where the examining finger can easily reach the uppermost limit of the disease, but for cases in which the growth has extended up the bowel to a point higher than this and for cases where the disease began high up in the rectum, the sacral operation offers possibilities of a cure which cannot be obtained in any other way. It adds to the number of operable cases and its possibilities should be carefully reviewed in every instance before a case is refused operation.

A description of the method of operating, incomplete as it must be in a paper of this length, does not present it in a very favorable light and is perhaps not such as to commend it in the minds of conservative men. It impresses one as an operation formidable in the extreme; but an opportunity of seeing the operation performed a number of times in Professor Albert's clinic and of seeing the cases afterwards in the wards, convinced the writer of its practicability. The comparative ease of its performance and the excellent opportunity for getting at the disease cannot fail to impress one, and the immediate results of the operation as shown by its mortality statistics are very much in its favor and are certainly such as to give it a claim upon careful consideration.

The operation has been in favor so short a time (three years) that there are, as yet, very few cases which have been watched long enough to be fairly reported as cured, but the operation is being constantly performed in the German clinics and in a few years will have a recorded experience which cannot be overlooked.

## NEPHRECTOMY FOR PYONEPHROSIS.<sup>1</sup>

BY J. W. ELLIOT, M.D.

I FIRST saw the patient in November, 1890, in consultation with Dr. Blaylock, of Nashua. She was a delicate woman, twenty-one years old and three years married. She had always had more or less pain in her right side, but had remained well up to one year before I saw her, when she was taken with chills. Then the bowels bloated, and there was obstinate constipation. A tumor appeared in the right side, which Dr. Blaylock thought was due to a fecal accumulation, and which disappeared with the use of cathartics. Her general health gradually failed; and three weeks before I saw her, her doctor found another tumor in her right side, which was thought to be ovarian. The doctor had noticed that the urine was milky-white, and said that the patient had just recovered from an attack of nephritis, at which time the urine had contained albumen. She had lost twenty pounds in the last year.

The patient was pale and looked badly. I found a tumor occupying the whole right half of the abdomen, extending from the liver down into the pelvis. It was dull on percussion, and semi-fluctuating. Per vaginam, a slightly enlarged fallopian tube could be felt, but the tumor could in no way be connected with the pelvic organs.

All the symptoms seemed to point to the kidney as the origin of the disease, but I declined to give an opinion before I knew the result of a careful examination of the urine.

Professor Wood, of Harvard Medical School, reported that there was a trace of albumen; that there was a large amount of sediment, chiefly pus and small round cells partly arranged in clumps, little blood, bladder or vaginal epithelium, an occasional small hyaline and granular cast. Diagnosis, chronic pyelitis. He also expressed the opinion that there was no interstitial disease. The amount of pus was two or three drachms in seven ounces of urine.

With this report it seemed probable that we had to deal with a suppurative disease of the kidney. Of course, there was the possibility that the ureter on the right side was obstructed, and that the pyelitic urine came from the left kidney.

I advised immediate operation, and planned to make an opening in the back and drain the abscess or whatever it might be.

When the patient was etherized on November 26th, at a private hospital, the tumor had an entirely different feeling; it was much less tense, more fluctuating and quite movable. I began to feel uncertain as to what it might be. Consequently I determined to begin the operation with an exploratory laparotomy, thinking that I could still drain through the back if it seemed best, after I had discovered what the tumor was. The abdomen was therefore opened in the median line, and a cystic tumor was found behind the per-

itoneum, pushing the colon over nearly to the median line. The peritoneum was incised in front of the colon, and the cyst drawn up and tapped with an exploring needle which brought out a milky-white fluid. Still in doubt, I opened the cyst, and dragging it forward, discovered that it was a sacculated kidney. As the cyst was large and not adherent, I thought a nephrectomy offered better chances than a nephrotomy with drainage and subsequent nephrectomy. I therefore determined to remove the kidney at once. Having enucleated the sacculated kidney the vessels were easily ligatured; in fact, the median incision was very important for this part of the operation; for the kidney being large, its pelvis had pushed nearly to the median line of the body. The ureter was brought up and fastened to the abdominal wound. The peritoneum which covered the kidney was stitched to the peritoneum on the opposite side of the median incision. This closed the abdominal cavity, and left the route open from the abdominal incision to the bed of the kidney. As there was no bleeding, no drainage-tube was inserted. This was a mistake as will appear later.

The tumor when removed proved to be a kidney dilated to the size of a child's head. The kidney substance was entirely destroyed leaving a series of large cavities, of which the walls were as thin as paper in some places and one-third of an inch thick in others. The pelvis was also much dilated; but the ureter was in every way normal, there being no evidence of dilatation or of stricture. The kidney contained a milky fluid which had a large sediment of pus.

There was no shock following the operation, but the patient suffered considerable pain from wind and tension on the ureter. No stimulants were given, and only a very little morphia for fear of irritating or diminishing the activity of the other kidney.

The urine which for months had been milky-white became normal in color immediately after the operation. In the first twenty-four hours fourteen and one-half ounces were passed; in the second twenty-four hours thirteen and one-half ounces were passed.

Dr. Wood examined the specimens from both days, and reported as follows: "Color, high; reaction, acid; specific gravity, 1.034½; urophæin, normal; indoxyl, increased; urea, much increased; uric acid, increased; chlorides, normal; earthy phosphates, diminished; alkaline phosphates, much increased; albumen, very slight trace; sediment, chiefly amorphous urates; large excess of renal cells, few blood globules and an occasional granular cast. Amount of urea, 3.894%." The second specimen showed in the sediment; "Few hyaline and granular casts. Most of which have a few blood globules and renal cells adherent. Amount of urea, 4½%. Both of these examinations show great concentration of the urine and slight congestion or irritation of the remaining kidney."

On the third day twenty and one-half ounces were passed; on the fourth day there were sixteen and one-half ounces of urine. On the fifth day the pulse and temperature were normal, and the bowels moved. On the seventh day the urine increased to twenty-one ounces, and then gradually to twenty-eight ounces on the thirteenth day.

On the seventh day the temperature began to rise in the evening, and on the twelfth day it reached 102°. On taking out the stitches, the wound was found swollen and tender. On tearing it open, a large quantity of pus welled out. A tender mass soon made its appear-

<sup>1</sup> Read at Meeting of the Surgical Section of the Suffolk District Medical Society, February 4th, 1891.

ance on the right side, in the cavity formally occupied by the kidney. The temperature continued to rise, and on the evening of the nineteenth day it reached 103°.

The next day I etherized the patient, and with an exploring needle found pus in the mass in the right loin. This was incised, and drained through the back. The next day the twenty-four hours' urine fell from forty-four ounces to eighteen. The temperature was 103½°. The pulse was 120. There was vomiting and a poor general condition. On the following day these acute symptoms subsided. The operation was completed in less than five minutes, and this severe constitutional disturbance shows how poor a subject for a surgical operation a person with a single hyperæmic kidney may be. As soon as the drainage in the back was established, the pus, which had continued profuse in front since the stitches were removed, immediately stopped, and came only through the back. The general condition improved rapidly. Convalescence then progressed without further incident. The patient sat up in five weeks, and went home in six weeks.

Professor Wood kindly made the following report on the urine just before she went home: "Albumen, the slightest possible trace; sediment, chiefly vaginal epithelium, excess of renal epithelium; an occasional blood globule; an occasional hyaline and fine granular cast; renal cells on most of the casts. The clinical examination shows only a little hyperæmia of the kidney."

## Reports of Societies.

### SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

GEORGE H. MONKS, M.D., SECRETARY.

REGULAR MEETING, Wednesday, February 4, 1891, DR. A. T. CABOT in the chair.

The CHAIRMAN showed three cases in which he had done a

#### CUNEIFORM OSTECTOMY FOR ANCHYLOSIS OF THE JAW.

The patients were aged thirty-two, twenty-seven and seven years respectively. In two of them the condition followed a blow on the chin. In the other patient it followed an otitis, the result of scarlet fever. In the two adult cases the disease had existed for from twenty to twenty-five years, while in the child, it had been but a little over a year's standing at the time of operation.

In the child the condyle was fixed in the socket by bony anchylosis, while in the two adults the upper end of the jaw, including the condyloid and coronoid processes, was changed into a mass of bone, and was welded to the base of the skull so that in these two cases the bone to be chiselled through was very wide and thick. The incision used was a horizontal one just below the zygoma, with a vertical one down over the neck of the jaw when more room was necessary. The scar that was left was very slight, and in two of the cases almost invisible. In none of them was there any paralysis of the facial nerve.

The motion of the jaw was excellent in all of the cases shown. In the adult, however, the lower jaw

was relatively undeveloped, so that the apposition of the teeth in the front of the mouth was not perfect. The contrast in this respect between these cases and that of the boy, in whom the operation had been done within a year of the establishment of the anchylosis, showed the great advantage of an early operation.

Dr. Cabot said that the patients shown were the last three out of six that he had operated upon for this deformity. The results in the other three patients, not shown, were better than in the two adults exhibited.

In regard to the operation, the chief danger lay in the chance of strangulation during etherization, for the fixed condition of the jaw prevents access to the tongue to pull it forward if it fell back in the mouth. In one of the adults this accident happened, and a hasty tracheotomy became necessary. After the tube was in the trachea the separation of the jaw was affected more easily and quickly than usual.

The after-treatment consisted in keeping the chiselled surfaces of bone widely separated by means of a cork between the teeth, thus allowing the soft parts to heal across, and interpose fibrous tissue in the desired joint.

He said that he thought this operation done with ocular inspection of the condition to be remedied was better than any of the operations done through the mouth. The only objection lay in the scar left by the outside operation, and he had brought the present cases partly to show how slight this scar was under antiseptic healing.

DR. J. W. ELLIOT reported a case of

#### NEPHRECTOMY FOR PYONEPHROSIS.<sup>1</sup>

DR. F. S. WATSON said that in this class of disease the question of choice of method of operation must be decided upon the peculiar conditions presented by each case, to a greater degree than in almost any surgical disease with which he was familiar. It was difficult to draw valuable conclusions from statistical study in this matter, except of the most general nature, and it was with these limitations that he would present the results of a study of a considerable number of renal operations taken from the reports of cases published during the last four years, and would submit his conclusions inferred from a study of these data, with reference to the choice of operation based upon the nature of the disease for which the operations were performed.

#### GENERAL CONSIDERATION OF MORTALITY OF RENAL OPERATIONS.

(1) *Nephrotomies*.—The total number of cases 153, 20 deaths (13%); lumbar nephrotomies for calculus, 71 cases, 4 deaths (5%); for conditions other than stone, 57 cases, 11 deaths (19%); abdominal nephrotomies, 12 cases, 2 deaths; method unknown, 13 cases, 3 deaths (23%).

Nephrotomy for conditions other than stone, in detail:

	Cases.	Deaths.	Per cent.
Pyonephrosis . . . . .	33	8	20
Hydronephrosis . . . . .	8	0	0
Cystic kidney . . . . .	4	0	0
Tubercular . . . . .	1	1	100
Injury . . . . .	1	1	100

(2) *Nephrectomies*.—Total, 176 cases, 57 deaths (30%); abdominal operation, 55 cases, 25 deaths (40%); lumbar, 75 cases, 21 deaths (28%); operation not mentioned, 46 cases, 11 deaths (23%).

<sup>1</sup> See page 457 of the Journal.

nephrotomy is the operation of choice. If the kidney is seen to be greatly disorganized at the time of this operation, or if for any reason the stone cannot be removed, nephrectomy should be at once performed if the patient's condition permit, and in this case the nephrectomy should be lumbar unless very extensive adhesions or other technical difficulties make its success improbable; in the latter the kidney should be removed by the abdominal incision. Subsequent nephrectomy may be performed if the result of the nephrotomy be unfavorable.

(2) In renal calculus the abdominal operation in the first instance, is indicated, if ever, in cases in which it has been impossible to locate the trouble in one kidney.

(3) Lumbar nephrotomy, as an exploratory operation, is permissible in cases of suspected calculus, in which, in the absence of corroborative diagnostic features, persistent or repeated attacks of renal colic occur.

(4) Nephrolithotomy should not be postponed in cases of renal calculus in which the diagnosis is assured, and in which there is failure of the stone to pass after a reasonable interval—for the reason that the danger of the operation increases in direct ratio to the continuation of the presence of calculus and the progress of renal disorganization due to it, while the results in early cases are exceedingly favorable.

(5) In cases of pyonephrosis and hydronephrosis due to causes other than stone, lumbar nephrotomy in the first place is in general the best operation, to be followed by nephrectomy if indicated later.

(6) Unless especially contraindicated, nephrectomy should be performed in all cases of sarcoma and benign tumors, and in cancer, if pain calls for the operation, or if it be discovered in an early stage of development. Abdominal nephrectomy is the method of choice in these cases.

(7) Little benefit can be expected from operation of any sort in tuberculous disease.

(8) Operation for floating kidney should be first nephrorrhaphy—nephrectomy if it fails and operation is still indicated.

DR. H. W. CUSHING: I would like to ask Dr. Watson upon what grounds he founded his conclusion that the abdominal operation was preferable in cases of tumor.

DR. WATSON: The preference for the abdominal operation in cases of tumors is founded, in the first place, on the difficulties presented in this class of cases, especially in some cases of cancer, by the adhesions, which render the lumbar operation much more difficult than the abdominal one; and also because in these conditions the abdominal method is attended with less mortality than the lumbar.

DR. H. W. CUSHING: I had understood, that for the smaller tumors the lumbar operation is elected, the abdominal being preferred in cases of very large tumors.

DR. WATSON: The larger the tumor the more preferable the abdominal operation becomes. The statistics of abdominal operations show more favorable results than those of the lumbar operation; and you cannot always predict before you get down to the kidney what sort of a growth, and what conditions are to be encountered.

The CHAIRMAN said, that, in the choice of operations for pyonephrosis, we should be guided not only by the comparison of rates of mortality, but quite as

much by the completeness of the final result. It may often be worth while to run a little additional risk for the purpose of obtaining a complete cure without a discharging sinus.

The plan of doing a preliminary nephrotomy to be followed later by a nephrectomy seemed to him applicable to many of these cases. It not only gives the patient a chance to gain strength for the final more severe operation, but it also reduces the size of the tumor and makes its final removal more easy. He thought that this combination of operations offered the patient a better chance of comfort afterwards than nephrotomy alone, and a better chance of recovery in severe cases than by nephrectomy alone.

DR. ELLIOT: I think there is one other thing to be considered in this question of nephrotomy first and nephrectomy afterwards, and that is that although it may be very desirable to do a nephrotomy first to save strength, yet nephrectomy cannot always be done later. The question which I had to decide was whether I should do this to save strength, or whether the chances were better by doing both operations at once. I am sure there are a lot of old discharging sinuses about Boston, and every surgeon who sees them knows that they do not heal up. The patients get very much run down, and although a nephrectomy might have been done yet the patients do not have it done, and they go about in a very miserable condition. There are two patients coming to the Out-patient Department at the Massachusetts Hospital now, who have had a discharging sinus in the back for years. They do not want anything done, so they will always remain invalids.

In tuberculosis of the kidney, I am sure if you do anything you should do a nephrectomy in order to get rid of the whole thing at once.

DR. WATSON'S statistics were very interesting and very impressive; but personally, in the choice between the operation in the back and the abdominal operation, my instincts would be in favor of doing it by abdominal section, in the first place because I am used to the operation and have no dread of opening the abdomen, and in the second place because I much prefer to know the exact condition before extirpating the kidney. This same question has come up in various other operations: It has often been maintained that it was better to drain purulent salpingitis than to extirpate the tube. The same question as to appendicitis was discussed a long time; and it seems to me that all these questions as we advance in surgery, come round to opening the thing wide, so that you can see it. I should almost always do a laparotomy for these cases, and I should never do a nephrotomy except to save kidney substance, or to save time and strength, as Dr. Cabot suggests. I say all this merely as my impression, because I have not had a large experience. I have only had two nephrotomies, and in both the sinus never healed. To back my opinion though, I have the experience of Mr. Thornton, who reported twenty-five cases in 1889 for all sorts of disease of the kidney. Only five of those cases died; twenty got well. They were for pus, for hydronephrosis, and for tumors of various kinds. Of these five cases that died, one died of apoplexy following the other; another had a malignant tumor which perforated the pleura. So his mortality would be at most twenty per cent., and I think it would be fair to rate it lower than that. In my own case I want to see what I am operating on, and make a thorough diagnosis, before I do anything; and

that, in difficult cases, can only be done by the abdominal method. There is also this to be said, that when a man like Mr. Thornton makes a very great improvement in mortality it deserves attention.

DR. W. J. OTIS gave a demonstration on the living subject, of his

#### METHOD OF HIGH RECTAL INSPECTION.

He remarked that when such an inspection is desired for purposes either of diagnosis or treatment, it is the practice of surgeons generally to forcibly dilate the anal sphincters under complete surgical anaesthesia. Dr. Otis claims that in those cases where there is no disease in the lower rectum to contraindicate, it is perfectly feasible to get a satisfactory view of the upper rectum without subjecting the patient to the ordeal of anaesthesia and forcible dilatation. This he successfully demonstrated on a male patient from his clinic at the Boston Dispensary. The anus was dilated and held open by the use of instruments which had been devised by Dr. Otis, on an entirely different principle from any in use at present for that purpose. [A description of these instruments will appear at a later date in the columns of the JOURNAL.]

Each member of the Section present was given an opportunity of witnessing the pneumatic dilatation of the rectum that takes place when the instruments are properly introduced, and also of seeing the *plicae recti transversales* (in this instance only two were visible, the lowest on the right) generally known as *Houston's valves*, but which as Dr. Otis has shown ("Anatomical Researches," etc., Leipzig, 1887) are in reality divisions between the sacculi of the rectum. Special attention was directed to this point in rectal anatomy, to the elucidation of which Dr. Otis has devoted much time and labor.

DR. PAUL THORNDIKE read a paper on

#### THE OPERATIVE TREATMENT OF RECTAL CANCER, WITH ESPECIAL REFERENCE TO KRASKE'S SACRAL METHOD.<sup>2</sup>

The CHAIRMAN: I would like to ask Dr. Thorndike the extreme upper limit in the most extensive successful Kraske resection, as far as he knows.

DR. THORNDIKE: It is well up to the sigmoid flexure. I do not know just the exact length of the bowel removed.

DR. H. W. CUSHING: Has Dr. Thorndike seen any cases where the transverse section of the sacrum (Lewy's method) has been employed?

DR. THORNDIKE: No; I never have. I have seen very few Kraske operations on the living, but many times on the cadaver. In the cases on the living subject the amount of gut removed varied from three to four inches, and was easy to get at in each case.

I had a note from Dr. Gerster of New York the other day. He has done the operation once and his case has done very well. Dr. Hockeneck, of Vienna, has had an experience larger than that of any other one man. He writes me that there have been fifty-five operations of this sort in Professor Albert's clinic up to date. He recommends the removal of as much of the sacrum as is indicated by the middle of one of the three dotted lines in the figure.

The CHAIRMAN: What practical disadvantages are there in the higher division of the bone?

DR. THORNDIKE: It is claimed that chiselling out

so much of the bone as the transverse line would indicate means prolapse of the gut afterwards even in a successful case.

DR. E. W. CUSHING: I would like to ask Dr. Thorndike if he could say a few words in reference to getting at the cancerous uterus through the chiselling away of the sacrum. Has he seen that operation?

DR. THORNDIKE: I have not seen it on the living subject. I have seen the dissection made a number of times. After the bone is chiselled away a large retractor is used to pull the rectum off to the left. When the original incision is made and the bone chiselled away, you come down upon the rectum, and with a very limited amount of loosening of its attachments you can pull the bowel away off to one side very readily indeed so as to get an astonishingly good view of the uterus from behind. It is really incredible the amount of anatomy you can see through that hole.

DR. E. W. CUSHING: Can you get at the broad ligaments?

DR. THORNDIKE: Dr. Hockeneck claims you can. He wrote me he had some cases which he is to publish shortly, so that we shall probably have a detailed report of this operation in its gynecological sense.

DR. H. W. CUSHING described the

#### METHOD OF CLAMPING THE INTESTINE DURING OPERATIONS INVOLVING THIS VISCUS.

devised by Dr. A. V. L. Brokaw, of St. Louis, Mo., and showed the instruments used, both the original wire clamp<sup>3</sup> which can be readily improvised in a few moments, and the latest pattern which is a more finished and satisfactory instrument. The method is an effective one, and the clamp surpasses all others in its simple construction, and in the satisfactory manner of accomplishing its purpose.

The advantages claimed by its originator are: (1) Simplicity of mechanism and ease of application; (2) absolute uniform compression of intestine, the blades closing parallel and not with the scissor-like action of most clamps; (3) rapidity with which it can be applied and removed; (4) precise regulation of amount of compression; (5) readiness with which the parts can be separated and sterilized.

#### THE OBSTETRICAL SOCIETY OF BOSTON.

CHARLES W. FOWNSSEND, M.D., SECRETARY.

MEETING, February 14, 1891.

DR. H. W. BROUGHTON read, by invitation, a paper on

#### SOME NOTEWORTHY CLINICAL FEATURES IN CASES OF MALIGNANT DISEASE: WITH REMARKS.<sup>1</sup>

DR. WM. D. HODGES reported, by invitation, a remarkable case which occurred at the Massachusetts General Hospital some years ago in the service of Dr. H. J. Bigelow, where enormous doses of morphine were tolerated. The patient, a girl twenty years old, with sarcoma of the leg, was given 2,024½ grains of morphine in five weeks, the largest single dose being 120 grains, and 180 grains was once given in two doses within forty minutes. The case will be reported later in full.

<sup>1</sup> See page 419 of the Journal.

<sup>2</sup> Weekly Medical Review, August 17, 1889.

<sup>3</sup> See page 453 of the JOURNAL.

DR. ABBOT spoke of the case of Colledge where two to three and one-half quarts of laudanum were taken weekly. In the case of a young man with cancer of the rectum just within the anus, with a constant offensive discharge of fluid, and continuous pain and discomfort, he had given great relief by introducing a French probe-pointed catheter (No. 14) through the stricture, adjusted to a Davidson syringe by a short piece of rubber tubing, pumping the colon full of water, and then, by reversing the syringe, sucking the water out again. This was done daily till the water came away clear. Under its use the patient had very little pain, recovered his appetite, and lived for a year in comparative comfort, being able to go about. He died suddenly from what was probably peritonitis, caused by a perforation of the bowels. Dr. Abbot believed that in some cases, at least, it was possible to substitute some inert substance for morphine, with the same result to the morphine taker, provided he believed he was taking morphine. He remembered a case at the Massachusetts General Hospital of an intelligent man with phthisis, who had frequent attacks of severe pain in the side, requiring doses of from one-fourth to one-third of a grain of morphine subcutaneously. Here water was suddenly substituted with the same relief of pain, and in a few days the patient was entirely cured of the attacks.

DR. SINCLAIR had similarly broken up the appetite for morphine by injecting water.

DR. F. B. HARRINGTON remarked that these cases suggest the importance of varying the drugs so as to avoid morphism. By the alternate use of such drugs as phenacetine, cocaine, etc., it might be possible to keep the dose within moderate limits. He asked whether the continued use of ether made the patient tolerant of it as in the case of morphine.

DR. BROUGHTON said that his patient was made very comfortable by the ether with less after-effect than from the large doses of morphine. He did not use it to profound anesthesia.

DR. GODDELL, of Salem, said he had recently seen a man, a worker in a shoe factory, who regularly took by subcutaneous injection fifteen to forty-five grains of morphine three or four times daily.

DR. BAKER said that one of Dr. Broughton's cases showed the importance of attending to any bloody vaginal discharge, after the menopause, as the majority of such discharges are of serious nature. Another point illustrated by this case is the failure sometimes of the micro-cope to determine the true nature of the disease. Of course, in many cases, the microscopic examination is of the utmost importance.

In a case of his own it was necessary to use twenty grains of morphine hypodermically, eight ounces of chloroform and five pounds of ether daily, for about a week. In this case the patient soon established a tolerance for ether, and hence chloroform was also used.

We can get rid of the necessity for the use of so much morphine by getting rid of some of the cancerous growth by operation, and even in extreme and hopeless cases a great deal of good can be done by the persistent and careful use of the curette, scissors and knife, with subsequent cauterization and use of chloride of zinc. He recalled a case where, seven or eight years ago, he had found a patient with the uterus firmly fixed by cancer. By the removal of the cervix and following up the disease on either side, so much

was removed that he was subsequently able to destroy the cancer by chloride of zinc faster than it was growing. Cicatrization took place and the patient is to-day well, and free from the disease.

DR. BLAKE spoke of a case of an opium eater where a solution of quinine was substituted for morphine, and the patient was unaware of the change. Another patient, a lady, was taking two ounces of laudanum three times daily. He told the druggist to reduce the strength four-fifths, but to keep the same color and taste. The patient did not notice the change. Another patient he was engaged in treating with Dr. J. P. Reynolds, did equally well with distilled water for morphine. As to ether toleration he remembered a case of chronic tetanus at the Massachusetts General Hospital during his house-officership, where the patient, a boy, was etherized every four hours for six weeks. The ether never failed to give relief and the patient bore it well.

DR. WM. A. DUNN read, by invitation,

#### AN ANALYSIS OF 1,168 CASES OF LABOR.<sup>2</sup>

DR. GREEN asked why it was that those women who could stay in bed only a week did apparently as well as those who are kept on their back for three weeks. He thought from his gynecological experience that this similarity in results was only apparent, for he believed that many cases of improperly involuted vaginal and abdominal walls, were due to the too soon getting up of the patient. The Lying-in Hospital examination shows that the uterus involutes more rapidly than the vagina, and that this slow involution of the vagina and abdominal walls is a sufficient reason for keeping the patient in bed for more than ten days.

DR. EDW. REYNOLDS spoke of the danger of giving chloral in large doses just before delivery, for in the absence of the pains the tolerance of the patient for this drug is annulled and there is danger of chloral poisoning. He recalled one case he had seen where this occurred and the patient became almost comatose.

DR. A. H. JOHNSON, of Salem, was surprised at the small number of cases of eclampsia. He had lately had a case of a primipara, who during a labor of fourteen hours complained of scintillation before the eyes, and of headache. At the conclusion of the labor she again complained of the same symptoms and also that she could not see. Fearing eclampsia, bromide was given, and on his return after two hours he found that she had had a convulsion and had bitten her tongue severely. One-fourth of a grain of morphine and ten grains of chloral were at once administered, and there was no return of the convulsions. Previous to the labor there had been no symptoms of renal disturbance, neither oedema nor headaches, and an examination of the urine after the convulsion showed no albumen.

DR. BLAKE said his rule was always to empty the uterus in cases of eclampsia, and when so doing, had never lost a case. He believed that many cases were lost by the failure of the physician to act promptly, and he particularly objected to delay in order to try the effect of drugs.

DR. DUNN in closing the discussion, wished to remark that he agreed entirely with the views just expressed by Dr. Blake.

<sup>2</sup> See page 451 of the Journal.

DR. STRONG reported a case of

LAPAROTOMY FOR REMOVAL OF THE UTERINE APPENDAGES IN A PATIENT MUCH DEFORMED BY SPINAL CURVATURES.

DR. BAKER said that the necessity of the operation for removal of the uterine appendages was very manifest in the case reported, and in properly and carefully selected cases he believed strongly in the advisability of such operation.

DR. STRONG wished to add that Dr. Whitney had examined the ovaries and found them much diseased by a cicatricial and hardening process and that they were also cystic. This condition of affairs could not have been benefited by medicinal treatment. The patient was given milk-punch, egg-nog, and as much stimulant as she could bear before the operation.

HARVARD MEDICAL SCHOOL ASSOCIATION.

MEETING for organization, held at the Boston Medical Library on Thursday, April 30, 1891.

The meeting was called to order by DR. J. R. CHADWICK, Chairman of the Committee of Organization, appointed at the preliminary meeting held on November 26, 1890. Dr. Chadwick was elected temporary Chairman, and Dr. R. W. Lovett, Secretary. The report of the committee was, on the motion of Dr. R. H. Fitz, accepted, and the committee discharged.

The Chairman was, on motion of DR. F. H. BROWN, authorized to appoint a committee to nominate officers. He appointed Drs. R. H. Fitz and J. A. Jeffries of Boston, Dr. Homer Gage of Worcester, Dr. C. E. Vaughn of Cambridge, and Dr. F. A. Sawyer of Wareham, who retired to prepare nominations for the Association.

It was moved by DR. F. H. BROWN, and unanimously carried, that a Harvard School Alumni Association be formed. Dr. Brown also moved that the articles of the constitution of the Association, as presented by the Committee on Organization, be taken up and considered *seriatim*. Carried unanimously.

Articles I and II were unanimously adopted. In the consideration of Article III, Section 1 (which read, that "all graduates may become members of the Association").

DR. J. C. WHITE thought that all graduates should not be allowed to enter the Association, but that some power of discrimination should be vested in the Council to prevent the entrance of such men as were notoriously of bad character. He thought that approval of the Council should therefore be a necessary qualification for membership.

DR. F. H. BROWN moved that the section be amended to read: "All graduates of the Harvard Medical School are eligible to be, and may become members if approved by the Council."

DR. G. E. FRANCIS thought that the Association should be open to all, and that graduation at the school should be considered the only qualification. He thought that in this way many difficult questions would be avoided.

DR. WHITE seconded the motion of Dr. Brown, and hoped that it would be carried.

DR. STEVENS thought that expulsion of unworthy

members should be provided for as well as the exclusion of such.

DR. DISBROW moved that the words "of good moral character and in regular standing" be inserted after the word, "graduates." This was not seconded.

DR. JONAH, of Eastport, hoped that the membership of the Association would be restricted to regular physicians. In the small towns he thought this a much more important matter than it would be in the cities.

DR. H. P. BOWDITCH thought that any renewal of the old quarrel between regular and irregular practitioners would be very unfortunate, and that the profession was to be congratulated that such animosities were rapidly becoming things of the past. The Massachusetts Medical Society had within a year or two recognized the diploma of certain homeopathic medical schools, as entitling the holder to apply to the censors for admission to the society, and the faculty of the Harvard Medical School has recently voted that the degree of M.D., from these same schools shall exempt from the Harvard admission examination, and furthermore, that certificates of attendance at these schools shall be accepted by the Harvard Medical School as evidence of time spent in medical study. It will thus be possible for students beginning their studies in these schools to enter the Harvard School with advanced standing on passing the required examinations. Dr. Bowditch expressed the hope that graduation at the school would be considered the only qualification for membership.

DR. CHADWICK hoped that no restriction would be imposed which would lead to unpleasant questions in the future.

DR. BROWN's motion was put by the chair and carried.

DR. STEVENS moved that a section be added after Section 1, to read, "By recommendation of the Council and by a two-thirds vote of the Association at any regular meeting, any member may be dropped." The motion was seconded; and upon being put, was carried by a vote of 21 to 18.

DR. G. E. FRANCIS asked for the decision of the chair as to what constituted membership in the Association. The chair was unable to decide.

DR. E. J. FORSTER moved that all who have signified to the committee their intention to join the Association and all who were present at the meeting be considered original members of the Association. Carried.

The succeeding articles were unanimously adopted until Article VII was reached, in which DR. STONE moved that the words "in writing" be stricken out after the word "notice." Carried unanimously.

Article VIII was adopted; and in Article IX the chairman inserted the words "or in print" after the word, "writing." The article was then adopted.

DR. G. E. FRANCIS moved the adoption of the constitution as a whole, which was unanimously carried.

The constitution as adopted is as follows:

CONSTITUTION OF THE HARVARD MEDICAL SCHOOL ASSOCIATION.

ARTICLE I.

The name of this Association shall be the "Harvard Medical School Association."

ARTICLE II.

The objects of this Association shall be to advance the cause of medical education, to promote the interests and increase the usefulness of the Harvard Medical School, and to promote ac-

quaintance and good-fellowship among the members of the Association.

#### ARTICLE III.

SECTION 1. All graduates of the Harvard Medical School are eligible to be and may become members if approved by the Council.

SECT. 2. By recommendation of the Council and by a two-thirds vote of the Society at any regular meeting, any member may be dropped.

SECT. 3. Every member shall pay an initiation fee of one dollar, and an annual due thereafter of one dollar; but any member may become a life member by the payment of twenty dollars in one payment, after which he shall be relieved from the payment of all dues.

SECT. 4. All physicians who have received any honorary degree from Harvard University shall be *ipso facto* honorary members of the Association. Honorary members may also be elected by this Association on nomination by the Council.

#### ARTICLE IV.

The officers of the Association shall be a President, ten Vice-Presidents, a Secretary, a Treasurer, and a Council of fifteen members. The President, Secretary and Treasurer shall be *ex officio* members of the Council.

#### ARTICLE V.

SECTION 1. The President, Vice-Presidents, Secretary and Treasurer shall be elected for the term of three years.

SECT. 2. The members of the Council, not members *ex officio*, shall be elected in classes, as follows: At the first meeting of the Association, three members of the Council shall be elected for the term of four years, three members for the term of three years, three members for the term of two years, and three members for the term of one year; and thereafter, at the annual meeting of the Association in each year, three members shall be elected for the full term of four years, to fill the places of those whose term of office shall then have expired.

SECT. 3. Vacancies occurring in any of the offices before the expiration of the respective terms shall be filled at the annual meeting next following the occurrence of such vacancies. The Council shall have the power to fill a vacancy in the offices of Secretary or Treasurer for the remainder of the current year.

SECT. 4. All officers of the Association shall hold their respective offices during the regular term thereof, and until their successors shall be elected and qualified.

#### ARTICLE VI.

The annual meeting of the Association shall be held at Boston, Mass., on the Tuesday preceding the annual Commencement of Harvard College; provided, however, that the Council shall have the power to appoint in any year a different time and place for the annual meeting, if deemed expedient.

#### ARTICLE VII.

The President or the Council shall have the power to call a special meeting of the Association at any time, provided that at least two weeks' previous notice be given to all members of the Association.

#### ARTICLE VIII.

SECTION 1. The executive power of the Association shall be vested in the Council, subject to the control and direction of the Association.

SECT. 2. The Council shall have the power to elect from its own members an Executive Committee of not less than three members, to whom may be delegated such powers as the Council shall deem expedient.

SECT. 3. The Council shall elect every year from its own members a "committee on the Harvard Medical School," and may elect such other committees from its own members or the Association at large as it shall, from time to time, deem expedient to carry out the objects of the Association.

SECT. 4. The Council shall have the power to appoint, from time to time, one or more Corresponding Secretaries in the different cities or towns of the United States and the British North American provinces. It shall be the duty and office of such Corresponding Secretaries to promote in their respective localities the objects and interests of the Association.

SECT. 5. The Council shall have the power to fix the number of members of the Association necessary to constitute a quorum for the transaction of any and all business, save that of amending the Constitution, and to fix also the number of their own members necessary to constitute a quorum of the Council.

#### ARTICLE IX.

The Secretary, Treasurer, the Council and the Committee on the Harvard Medical School shall make and submit to the Association, at its annual meeting in each year, reports in writing of a printed form of their respective duties for the preceding year.

#### ARTICLE X.

The Constitution may be amended by a majority vote of all

the members of the Association present at the annual meeting, or at any special meeting called for that purpose, notice of such amendment having been given in the call for the meeting.

The Committee on Nominations then reported the following names, which list was unanimously elected:

President: J. R. Chadwick, of Boston. Vice-Presidents: J. G. Webster, of Augusta, Me.; Chas. P. Bancroft, of Concord, N. H.; A. H. Johnson, of Salem, Mass.; V. O. Taylor, of Providence, R. I.; F. R. Sturgis, of New York; R. T. Edes, of Washington, D. C.; James W. Flint, U. S. Navy, Washington, D. C.; W. A. Haskell (President Illinois State Board of Health), Alton, Ill.; Charles E. Briggs, of St. Louis, Mo.; G. H. Powers, of San Francisco, Cal. Secretary: R. W. Lovett, of Boston. Treasurer: Walter Ela, of Cambridge. Councilors: for four years, G. E. Francis of Worcester, L. R. Stone of Newton, C. F. Folsom of Boston; for three years, W. S. Bigelow of Boston, F. M. Weld of Jamaica Plain, S. D. Presbrey of Taunton; for two years, Edward Wigglesworth of Boston, Alfred Worcester of Waltham, J. T. G. Nichols of Cambridge; for one year, F. H. Brown of Boston, C. C. Tower of Weymouth, C. G. Carleton of Lawrence.

Dr. Bowditch moved that this election be substituted for the one which should regularly occur in June, 1891. Carried.

The CHAIRMAN then read some letters from members at a distance; and at one o'clock the meeting adjourned.

Graduates of the Medical School who have not received invitations to join the Association will confer a favor if they will write the fact to the Secretary, Dr. R. W. Lovett, 379 Boylston Street, Boston.

## Recent Literature.

*Human Magnetism. Its Nature, Physiology and Psychology. Its Uses, as a Remedial Agent, in Moral and Intellectual Improvement, etc.* By H. S. DRAYTON, LL.B., M.D., 12mo, pp. iv, 167. With illustrations. New York: Fowler and Wells Company, 1889.

Of making many books on hypnotism there is verily no end. This one has been made chiefly by the aid of the scissors, and not a very discriminating pair at that, for the clippings are of all sorts, and include the thorough work of Tamburini and Charcot and the theorizings of the most imaginative and least trustworthy of the hypnotism enthusiasts. What there is original in the work is slight, and it is devoted principally to showing how hypnotism corroborates the truths of phrenology. Hypnotism has always been in rather bad company, and in this work it still remains in it.

*The Treatment of Syphilis of the Nervous System.* By JULIUS ALTMAN, M.D., M.R.C.P., Lond. 12mo, pp. 35. London: Longmans, Green & Co. 1890.

This is a reprint of a paper read before the International Medical Congress at Berlin last summer. It contains little that is especially new or valuable, and dwells chiefly upon the advantages of the periodical and long-continued injection of small doses of mercury, which the author employs with lanolin and carbolized oil.

## AMERICAN MEDICAL ASSOCIATION.

THE FORTY-SECOND ANNUAL MEETING, HELD AT  
WASHINGTON, D. C., MAY 5-8, 1891.

## GENERAL SESSION. — FIRST DAY.

THE President, DR. W. T. BRIGGS, of Tennessee, in the chair.

The proceedings of the forty-second annual meeting of the American Medical Association were commenced in general session held at Albaugh's Opera House, Washington, by an

## ADDRESS OF WELCOME

to the members and delegates by the Hon. J. W. Ross, one of the commissioners of the District of Columbia.

He characterized the Association as representing a constituency more numerous and powerful than any other on the face of the globe, and one whose influence could not be over-estimated. No similar organization ever occupied the vantage ground held by the Association for the discussion of topics calculated to enlarge its usefulness and power. One of the primary objects at which it was aiming was the promulgation of such legislation as would tend to strengthen the profession in the performance of its duties. As a member of the bar he had often marvelled at the fact that the common law which respected the confidence which should exist between counsel and client did not extend the same privilege and protection in the case of the physician and his patients. If any communication should be absolutely sacred and beyond the inquisition of the witness-stand, it should be the statements made by an individual to his medical advisor. He thought that the time had come when any suitably expressed statements of the rights and requirements of the medical profession in this matter to the great body of law-makers in Congress would be treated with the most profound respect.

## THE PRESIDENT'S ADDRESS.

In the course of his address the President reminded his hearers that they were met solely for the promotion of science and for the good of the human race, to maintain the honor and dignity of the profession, and to hold aloft the flag of honorable medicine. They were there to lay their contributions, the results of study and observation, upon a common altar for the common good; to worship at the sacred shrine of medicine, and to renew their fealty to the noble profession to which they had devoted their lives and linked their fortunes. As physicians they had an almost superhuman mission to fulfil. The chief object of their professional work was to preserve life and ensure health. The goal of their ambition and desire was almost at the end of human capacity. It was their province as well as desire to know all the secrets of organization. They would have the formative crystal and the germinal spot made transparent. They would enter the microscopic world and witness the wonders therein revealed, and would, if possible, search into and unravel the very mysteries of the vital principle. To this perfect knowledge did they aspire. It was doubtful if man's intellect, great as it was, could ever compass all that he so earnestly desired, yet by constant and faithful work he might approach nearer and nearer to its consummation. In every part of the habitable world blessed with light of civiliza-

tion, active, busy members of the profession, endowed with high culture and incited by the noblest resolves, were enthusiastically engaged in unravelling the mysteries of disease, and seeking means and methods of treatment for the mitigation and relief of suffering, and the prolongation of life. That the full benefit of the labors of American physicians might be attained and utilized, it was essential that the members of the profession scattered over an area of country of almost inconceivable magnitude, should be brought into associated action, and be organized into a body whose influence might be exerted over the length and breadth of the land until a correct and noble sentiment was engendered in the mind of every member of the profession.

One of the great benefits conferred by the association was the establishment of an *esprit de corps* in the profession by the preparation and adoption of a code of ethics, which comprised the great principles of truth, honor and justice, in regulating the relations of physicians to each other, to their patients and to the public. This should be and was the written law, clearly defined and of acknowledged force and effect, that prevailed from one end of the country to the other. It formed an impassable barrier between the sheep and the goats, the clean and the unclean, the physician and the charlatan. The strict observance of this code had done more than anything else to maintain harmony in the profession, and to elevate it in the public estimation. It embodied the true spirit of the golden rule, "Do unto others as you would be done by." Every one who entered the profession should be provided with a copy of the code, and should make it the guide of his medical life. It would serve as a talisman to the young physician and would be the best safeguard against snares and pitfalls. It would seem that every honorable and high-minded member of the profession would be willing to endorse and be controlled by this code. It was to be regretted that there were some who undoubtedly possessed a high order of talents and were justly distinguished, who had still an utter repugnance to the observance of certain parts of the code, and who held themselves aloof from the Association in consequence. These gentlemen were probably as proud of the noble profession to which they belonged as any, and were equally as anxious for the advancement of its interests, but could they consciously affirm that the motives by which they were influenced were pure and unselfish? Should these members put their opinion against the unbiased and unselfish judgment of the wisest and most experienced in the profession, nine-tenths of whom were guided in their actions by the spirit and letter of the code?

The fundamental and chief object of those who had originated the Association was the improvement of the American system of medical education and the elevation of the standard of requirements for the professional degree. Never was there a greater expenditure of effort illumined with genius and learning to accomplish these two great objects, and though many of the ideas were, in a country diversified in character and extent, probably somewhat Utopian, there had been a gradual elevation of the standard of education fully equal to the progress of the country in every other department of human learning. The speaker was ready to maintain that the advantages and facilities for medical instruction in this country, even at the

present time, were quite equal to those of any other, and that the medical colleges had produced as able, learned and successful practitioners as ever graduated from other institutions. While he was willing to admit that their transatlantic brethren had excelled in experimental work, this country had taken the lead in all the practical departments of medical science.

Now that the College Association had adopted all the requirements for improved medical education which the Association had been so long urging, and for which, in fact, it was established, it was eminently proper and important to pass a resolution, that after the changes contemplated had gone into effect no medical man who had received a degree from a college which had not adopted the improved method of teaching, and no professor or *attaché* of such college, should be eligible as delegates or members of the Association. This great moral support was due to those colleges which had so heartily taken up the burden which the Association had for nearly half a century carried on its own shoulders.

It might be well to call attention to the fact that original research and experimental investigation had not received the attention from American physicians which their importance demanded. The Government, while the most liberal and best in the world, had never seemed to comprehend that the cause of science would be greatly advanced and its own honor increased by the establishment of schools for original investigation and experimental research. It had not kept pace with other enlightened governments in scientific enterprises. Such work must in the very nature of things be left, for the present at least, to the progressive spirit which animated the universities and to private laboratories which were being established in different sections of the country. It would probably be advisable to establish a Section of Experimental Research, which would tend to advance science and be greatly to the interest of the work of the Association.

It had been a happy conception of one of their most distinguished presidents to make the establishment of an Association journal the burden of his inaugural address, and so powerfully did he impress this upon the minds of the members that a journal had sprung into existence which had in a short time given evidence of its power in the advancement of its purposes. It might require years to bring it to the desired standard. To effect so desirable an object it was necessary to make provision for an ample annual income. Nothing less than seventy-five to one hundred thousand dollars should be considered ample. Next in importance to its financial needs was the selection of an editor, able, learned and highly endowed with editorial tact and business qualifications, who would devote all of his time and talents to his editorial duties. He should be empowered to spend money liberally in obtaining scientific material, original communications, translations and reviews from every part of the world. He should have absolute control in the selection of matter for the journal. To such an editor such a salary should be given as would render him independent. The sum should be not less than ten or fifteen thousand dollars a year. The necessary funds could, by proper exertion, be easily raised, and would not only sustain the journal in the best style, but would afford a sum in addition which could be used in many ways to the advantage of the Association. The future location of the journal was a matter of such importance as to re-

quire their careful consideration. Its weal or woe might depend upon the action taken at the present meeting. It had been suggested that the journal of the Association should be removed to Washington, and it had been determined to submit the question to the members of this session. He would beg the delegates and members of the Association to consider well every side of this question before committing themselves to a vote. The journal has now its home in Chicago, and has been there for eight years. It had already become the peer of any of the great weeklies of the country, and if properly sustained by the profession, and wisely and energetically conducted by its managers, it would become the recipient of the best thought of this country, and the worthy exponent of the American profession. It had been proven that it could be more economically published in Chicago than in Washington, which latter city was by no means an important, scientific or professional centre. But it was the great centre of American politics to which everything was made subordinate, and it would be impossible, if the journal of the Association was published in the city, to prevent its becoming contaminated by the political air.

(To be continued.)

#### OFFICERS OF THE AMERICAN MEDICAL ASSOCIATION FOR 1891-92.

THE following officers of the Association have been elected for the ensuing year: President, Dr. H. O. Marcy, Boston; Treasurer, Dr. W. E. Taylor, California; Secretary, Dr. W. B. Atkinson, Philadelphia; Chairman of the Committee of Arrangements, Dr. H. O. Walker, of Detroit, Mich., at which place the meeting of next year will be held, commencing on the first Tuesday in June, the 7th.

#### FOREIGN BODIES IN THE ŒSOPHAGUS.

POLIKIER gives a very simple method of diagnosis and treatment applicable to some cases of foreign body in the œsophagus.<sup>1</sup> He had been asked to see a child of five years of age that had swallowed a piece of money about the size of a five-cent nickel piece. Not being able to find anything by the internal examination of the throat, he tried to see what he could do by an external method. Placing his finger in the space between the trachea and the sterno-clavido-mastoid muscle on the left side, he made an effort by pushing upward. While remaining in this space, by careful touch he was able to find an elevation a little below the cricoid cartilage, which was no doubt the foreign body. While with one hand he tickled the child's throat, he made a sort of massage by pushing against the body upward and backward, when in a few seconds the child vomited the coin. The second case was one where the child had swallowed a silver piece (about the size of a quarter dollar), and the same manipulation succeeded in making the child vomit the piece. The conclusion that can be drawn from these two cases is that, notwithstanding the deep position of the œsophagus, it is possible to find a foreign body, in some cases, by external manipulation, and the simplicity of the method is worth a trial, rather than the usual efforts tending to push the body downward.

283 WASHINGTON STREET, BOSTON, MASS.

REPORTS ON TREATMENT WITH TUBERCULIN.

OUR professional brethren in London are beginning to report the results of their experiences with tuberculin to the medical societies. Dr. Bristowe, of St. Thomas' Hospital, lately addressed a metropolitan branch of the British Medical Society on the subject.<sup>1</sup> Time and observation of the results of others, rather than any extensive personal experience, seem to have confirmed him in the scepticism and distrust with which he has from the first regarded the treatment. In the discussion which followed Dr. Bristowe's paper, Dr. Hector Mackenzie stated that:

"He had watched the effect of treatment on patients at the Brompton Hospital under the care of his colleagues. Some of these patients, before and after the treatment, had been under his own care, and he had therefore had the best opportunities of forming an opinion as to the effect of the treatment. He had seen no case of cure. Some were *in statu quo*, some were distinctly worse, some had proved most intolerant of the remedy. In some cases in which there was apparent improvement, the signs of disease were more extensive, and pointed to more active disintegration going on in the lung. The results of the treatment with Koch's remedy compared most unfavorably with the results obtained on the ordinary lines with tonics, cod-liver oil, good food, and good hygienic surroundings. What had been the practical outcome of the whole matter? Honors and decorations to Professor Koch, a short harvest to the Berlin hotel keepers, loss of time and money to medical practitioners in all parts of the world, a few doubtful cures of lupus, hundreds of patients made to undergo a course of treatment which, at least temporarily, increased their sufferings, the hopes of thousands raised to the highest pitch only to be bitterly disappointed, and a number hastened to the grave."

On the other hand, Dr. Heron, of the City of London Hospital of Diseases of the Chest, reports<sup>2</sup> his personal experience of the treatment in thirty-seven cases of pulmonary phthisis, five of lupus and one of anaemia, in a paper read April 20th at a meeting of the Medi-

cal Society of London. The doses ranged from one to one thousand milligrammes, and the injections in pulmonary cases were repeated, as far as possible, daily. In general, Dr. Heron considered that the results were decidedly encouraging; all the cases of lupus had *improved*, and of the thirty-seven cases of pulmonary phthisis only ten had failed to show decided benefit. Koch's instructions as to selecting early cases for treatment being adhered to, Dr. Heron concludes that: (1) there is practically no risk in the use of the remedy, provided that the dose is gradually increased, and (2) that it is not of absolute diagnostic value.

In the discussion which followed this paper a variety of opinions were expressed. Dr. Theodore Williams found the results in fourteen cases of pulmonary phthisis under his own care not at all satisfactory. Dr. Radcliffe Crocker had found that in his own experience with lupus, notwithstanding that in some cases, *for a time*, every progress seemed to be made towards a cure, the injections alone did not compare at all favorably with scraping alone. He was disposed to think that tuberculin in lupus must be regarded as only a complementary treatment.

Mr. Hutchinson<sup>3</sup> takes much the same position in regard to lupus; in some cases he feels compelled to admit that the results were, after long perseverance, excellent, yet, even of the best, he cannot assert that he has seen a single one in which the disease was cured.

At the recent meeting of the German Congress for Internal Medicine at Wiesbaden several clinicians reported early cases of pulmonary tuberculosis as practically cured by tuberculin. V. Ziemssen, of Munich, with an experience of more than one hundred mixed cases concludes that Koch's discovery still deserves the fullest confidence, and that, in spite of a possible necessity for modifications, it will still afford suffering humanity much alleviation. Fürbringer, of Berlin, out of one hundred mixed cases reports five per cent. as cured of all active symptoms, and forty per cent. as unquestionably much improved, and he thinks the advantages outweigh any drawbacks of the method. V. Jaksch, of Prague, still holds that tuberculin has considerable value as a means of diagnosis, but confesses himself disappointed in its therapeutic action.<sup>4</sup>

We publish in this issue some cases in Boston in which the results are not favorable, neither were most of the patients very favorable for treatment. We shall shortly give our readers further reports and further discussions. The last word on the treatment has not yet been said. There is room for differences of experience — of application, of interpretation and of theory. We sympathize as little now with those who are anxious to have the whole treatment thrown aside as utterly worthless, as we did previously with the ultra enthusiasts, who predicted that tuberculosis was soon to be a disease of the past.

## BILIARY LITHIASIS.

At the Tenth Congress of Internal Medicine held at Wiesbaden, April 6th to 10th, the subject of biliary lithiasis was presented in both its medical and surgical aspects, Naunyn, of Strasburg, referee; Fürbringer, of Berlin, co-referee.

The first speaker regretted that he could give only negative data respecting the pathogeny of the question; our knowledge of the physiology of the bile thus far furnishes no light as to the causes of the production of biliary calculi. One thing has been determined by statistics: this affection is much more frequent in women than in men, and especially in pregnant women and women that have borne children. Naunyn attributes a preponderant influence to stagnation of bile in the bile ducts and gall bladder, and shows how in females the mode of dressing, and particularly the use of tight corsets, impede the flow of bile and promote its stagnation; pregnancy, moreover, does the same by hindering the play of the diaphragm.

Biliary lithiasis is also frequent in the aged; this has been attributed to enfeeblement of the unstripped muscles of the bile ducts whose peristaltic contraction has been proved to be so efficacious—at least so far as the common bile duct and the gall bladder are concerned—in birds. It is to atony of the unstripped muscles that we must refer the paresis of the intestines and bladder so frequent at an advanced age. Chareot has observed atrophy of the smooth muscles of the walls of the larger bile ducts in old men. It is easy to see that atony of these involuntary muscles would favor bile-stasis and cholelithiasis.

The therapeutics of cholelithiasis, according to Naunyn, remains still unsatisfactory. Alimentation, he affirms, has no proved influence on the formation of biliary calculi; no kinds of food either promote or hinder. None of the substances designated as cholagogues really have any action of this kind. We cannot count on alkalies to facilitate the solution of the salts of bilirubin, seeing that they are neutralized before reaching the bile, even after the ingestion of considerable doses.

With regard to the medical and hygienic treatment this speaker had but little to say. As no kind of diet makes much difference, so there is no special diet for the subjects of biliary lithiasis, but meals should be regular—not too far apart—and all excesses should be avoided, as well as use of indigestible food, as tending to favor the accumulation of bile. The alkaline chloride mineral waters were recommended, not as cholagogues or solvents, but as stimulants of the peristaltic movements and energizers of the intra-abdominal circulation.

Fürbringer, co-referee, had found that cholelithiasis was often latent. He had, during the last five years, noticed gall-stones at autopsies in five hundred cases, where there had been no symptoms during life suggestive of any such trouble.

Among the principal symptoms which proclaim the passage of calculi, the hepatic colic, the chill, the

vomiting, the collapsus, etc., are the most characteristic. The seat of the pain is generally referred to the epigastrium; this pain is accompanied by irradiations up and down, and great sensibility to pressure over the hepatic region. Almost always hepatic tumefaction coexists with icterus when the latter is present. Fully fifty per cent. of patients have some fever, with generally a slow pulse. Jaundice never appears at the onset of an attack, and is never seen when the obstruction is in the cystic duct. In thirty-one only out of forty-one cases was there jaundice, varying in intensity. The intervals between the attacks are sometimes marked by good health, sometimes by want of appetite, indigestion, constipation, general muscular feebleness, etc.

The persistent enclavement of a calculus in the bile passages is diagnosed by the presence of the tumor, the absence of jaundice and of bile pigment in the urine, by the biliary character of the vomited matters, etc. Occlusion of the choledochus by a calculus is revealed by chronic icterus and the resulting phenomena of cholemia. Among the clinical symptoms of the secondary inflammatory process, coming on at the site of the enclavement, and among the consecutive manifestations of this lesion, it is less the angiocholetis or the cholecystitis than the divers suppurative forms of hepatitis and the consequences of perforations which constitute the symptomatic *tableau* of the affection.

The "intermittent hepatic fever" of Chareot, associated with icterus, with local pains, with tumefactions, plainly perceptible, presents considerable diagnostic value.

As for the prognosis of this affection, statistics give thirty-four per cent. of conditional cures, forty-two per cent. of ameliorations, ten per cent. of failures, and fourteen per cent. of deaths. Of six cases incurable by medicinal means and subjected to surgical treatment, four were saved by operation (Fürbringer's statistics).

As a therapeutic means indicated by the existence of the hepatic colic, there is still nothing equal to opium or morphine, exhibited in sufficient doses to quell the pain. The "lithontriptic" treatment is an absurdity; there are no solvents for biliary calculi. Cold enemata aid by stimulating the expulsive forces. Experience proves the alkalies and alkaline mineral waters to be of some therapeutic efficacy. The treatment by salicylate of soda and by olive oil deserves careful trial. The last method has for its end to make a veritable lavage of the liver with the oil (*sic*); agglomerations of saponified fat are produced which may be found in the stools in the state of pseudo-calculi. The oil is oftener tolerated than one would suppose, yet it sometimes occasions a painful dyspepsia.

As for dietetics, Fürbringer relies more on temperance than on the prescription or proscription of certain aliments. He would only forbid a diet too rich in fats or in sugar, as well as the use of much alcohol or alcohol of bad quality. Regular action of the bowels

should be secured. Lukewarm baths, an invigorating atmosphere, abstention from over-fatigue, may be of great utility.

As for surgical intervention, it certainly offers hope in many cases. Yet it must be remembered that the cutting operations are not unattended with danger, as one out of every six or seven dies. As in the case of ileus, "it may be said that the results of medical therapeutics are not yet sufficiently bad, and those of surgical therapeutics sufficiently brilliant to actually open up a very large field to the operators." Certainly as a last resort, to save life, or to obtain relief from intolerable suffering, or to rescue from the danger of pyæmia or cholæmia, an operation may be imperatively demanded.

#### HARVARD MEDICAL SCHOOL ASSOCIATION.

GRADUATES of the Harvard Medical School have long felt the need of an organization to keep alive their interest in the institution which launched them on their professional career. This need has now been supplied by the founding of an alumni association, an account of which will be found in another column. How real this need was, and to what an extent the old scholars take pride and interest in the School and the University may be inferred from the fact that over six hundred graduates responded to the circular of the committee of organization, and from the enthusiasm shown at the meeting of last Thursday. There is, to be sure, nothing new or original in the idea. Many medical schools have similar organizations; and even among the professional schools of Harvard University, the Law School Association has for some time enjoyed a large share of popularity and influence.

The object of this new Association is to furnish opportunities for enjoyment and sociability among the graduates, and to increase and foster the interests of the Medical School and University. All graduates of the School, of good moral standing, are eligible for membership, and there is every reason to believe that a large proportion of the alumni will be enrolled. The Association has been started under favorable auspices, and we offer our best wishes for its success.

#### MEDICAL NOTES.

**TYPHOID FEVER IN PHILADELPHIA.**—During the months of March and April there were 1,157 cases of typhoid fever reported in Philadelphia with 226 deaths, a mortality of about twenty per cent. That part of the city which is supplied with water by direct pumpage from the Schuylkill River has suffered the most, although recently the epidemic has shown a tendency to spread.

**THE NATIONAL ASSOCIATION OF RAILWAY SURGEONS** held its fourth annual meeting at Buffalo, April 30th and May 1st. Several papers were read, and the following officers elected for the coming year: President, J. H. Murphy, St. Paul, Minn.; Secretary, E.

R. Lewis, Kansas City, Mo.; Treasurer, R. H. Reed, Mansfield, Ohio. It was voted to hold the next meeting at Hot Springs, Va.

**CHANGES IN DIFFERENT MEDICAL FACULTIES.**—The chair of Surgery in the Rush Medical College made vacant by the death of Dr. C. T. Parkes was divided, and Nicholas Senn, M.D., of Milwaukee, and Roswell Park, M.D., of Buffalo, elected to the professorships. Dr. Park has declined the offer. The trustees of the Jefferson Medical College, Philadelphia, have appointed H. A. Hare, M.D., Professor of Therapeutics and Materia Medica, to succeed Dr. Roberts Bartholow. Dr. J. M. Da Costa has resigned the chair of Practice of Medicine in the same college. J. M. Baldy, M.D., has been elected Professor of Gynecology in the Philadelphia Polyclinic. Dr. Edward A. Ayres has been elected to the Professorship of Obstetrics in the New York Polyclinic.

**PHYSICIANS AND THE SECULAR PRESS.**—The names of a large number of medical men in different parts of the country seem to have recently found their way into the daily papers in connection with the subject of the propriety of physicians allowing their names to appear in the secular press. In Iowa, an anonymous circular was distributed, containing clippings, which was intended to show that the men who most emphatically insisted on the strict enforcement of the code, were the most liberally advertised. The result has been a wide publicity of the subject, and a suit for damages.

**POPULATION OF GERMANY.**—According to the census taken December 1, 1890, the population of the German Empire was 49,422,928. During the last five years the increase has been 2,565,138, exclusive of the island of Heligoland, which added 2,086 to the population.

**PIPERAZIDINE.**—It is stated in a German pharmaceutical journal that piperazine dissolves uric acid more readily than any other substance of a basic nature. Urates of lithia requires 368 times its own weight of water to dissolve it, but urate of piperazine dissolves in fifty times its weight of water.

**VACCINE LYMPH FROM GOATS.**—From the report of the Vaccination Institute of Vienna, it appears that during the last year experiments were made as to the possibility of obtaining vaccine lymph from goats. The experiments are said to have been very successful. At a recent meeting of the sanitary council a report on the same subject was presented by Professor Oser, and Herr Umlauf, a veterinary surgeon.

**EUTHANASIA.**—The *Province Médicale* publishes a letter from a French country practitioner, who reports that he was summoned to a case of hydrophobia by the parents of the sufferer, with the earnest request that he should immediately kill the patient. The request was made perfectly seriously, without any question but that it was the proper thing to do.

**A BURLESQUE ON MEDICAL LEGISLATION.**—The following are extracts from a bill which is said to have

been introduced in the Texas Legislature, not with a view of having it passed, but as a burlesque on some other legislation: *Be it enacted, etc.*, that all pills prescribed or administered by any physician in the State of Texas shall be of the uniform weight of five grains, and shall be administered in doses of one pill each and every hour for not less than four consecutive hours nor more than eight hours. All doses of liquid medicine shall be of fifteen drops each, one dose every consecutive hour for not less than three nor more than six hours. When one drop of medicine is diluted in one barrel of water, the dose shall be one wineglassful; if one drop from the first barrel be diluted in another barrel of water the dose shall be one beer-mug full. The fees of all physicians shall be as follows: For each visit to a patient, fifteen cents per pill per mile and twenty cents per liquid dose per mile for the first three miles, and two-thirds of said several rates for each additional mile in excess of three miles. In case of parturition the charge shall be five cents per mile and ten cents per hour for one child, five cents per mile and seven cents for twins, and five cents per mile and five cents each for a litter. In all other cases the fees shall be fixed by the commission hereinafter provided for. It shall be the duty of the governor to appoint a commission consisting of three citizens of this State, who shall have full power to make any and all regulations concerning the practise of medicine. No person who has ever studied or has any knowledge whatsoever of materia medica or any of its branches, shall ever be appointed upon said commission. The rules requiring bills to be read on three several days are suspended, and the president of the Senate and the speaker of the House are each required to take three pills, and this act shall take effect from and after their passage.

#### BOSTON AND NEW ENGLAND.

**DEATH-RATE IN BOSTON.**—The number of deaths for last week was 241, a death-rate of 27.9. This is larger than any week since last August, but from an analysis of the causes of death it would appear that the increase is largely accidental, and not due to any very marked increase in acute lung diseases or other complications of influenza.

**SMALL PARKS.**—A Committee of the Boston City Government gave a hearing last week on the petition of Robert Provan, M.D., and others, that the city set apart a few open spaces in the tenement districts, from half an acre to two acres in size, which would furnish places for recreation and sports.

**BOSTON MEDICAL ASSOCIATION.**—The annual meeting of the Boston Medical Association was held at the Medical Library on May 4th, at 4.30 p. m., Dr. Francis Minot in the chair. The Secretary reported that thirty-one new members had joined during the past year, and that financially the Association was very prosperous. Officers were elected as follows: Standing Committee, Dr. Francis Minot, Dr. Buckminster Brown, Dr. J. Collins Warren, Dr. Charles P.

Putnam, Dr. Vincent Y. Bowditch; Secretary and Treasurer, Dr. Charles L. Scudder, 94 Charles Street.

**PUBLIC RESERVATIONS.**—A bill has been reported to the Massachusetts Senate to incorporate the trustees of public reservations for the purpose of acquiring and opening to the public, under suitable regulations, beautiful and historical places and tracts of land in the State.

**VITAL STATISTICS FOR MAINE.**—“An Act to provide for the registration of vital statistics” was passed at the session of the Maine Legislature just closed. The act will take effect on the first day of January, 1892. Its provisions are very nearly like those of the New Hampshire law.

**BERKSHIRE DISTRICT MEDICAL SOCIETY.**—The annual meeting of the society was held April 29th, in Pittsfield, Mass. The following officers were elected: President, Dr. H. Bushnell, of North Adams; vice-president, Dr. A. T. Wakefield, of Sheffield; secretary, Dr. Henry Colt, of Pittsfield; treasurer, Dr. W. L. Paddock, of Pittsfield; librarian, Dr. W. W. Leavitt, of Pittsfield; commissioner on trials, Dr. F. K. Paddock, of Pittsfield.

#### NEW YORK.

**COLLEGE OF PHARMACY.**—The sixty-first annual commencement of the New York College of Pharmacy took place at the Metropolitan Opera House on the evening of April 27th. There were 124 graduates, and a number of prizes were awarded.

**THE LAKES IN CENTRAL PARK.**—A report recently made by Sanitary Inspector and Assistant Chemist to Sanitary Superintendent Ewing, of the Board of Health, in regard to the condition of the lakes in Central Park, shows that the one in the lower part of the park near 53th Street, is very seriously contaminated by sewage. The other lakes were found to be in fairly good condition.

**THE REV. DR. GEORGE W. BOTHWELL,** of the Church of the Covenant in Brooklyn, who on April 18th, accidentally swallowed the cork of a medicine bottle, which passed into the trachea and thence into the left bronchus, died of exhaustion on May 3d, two weeks and one day after the accident. On the day after he swallowed the cork, he preached two sermons; and it was not until the evening of April 20th that he decided to seek medical advice. Three days later he was taken to the Brooklyn City Hospital, where Dr. Rushmore opened the trachea and performed three unsuccessful operations for the removal of the cork. Had the patient's strength permitted it, the attempt could have been made to remove it by resection of two ribs and cutting down upon the bronchus. The autopsy showed that the cork had become impacted in the bronchus in the position previously suspected. The pathological conditions found were: septic broncho-pneumonia, recent pleuritic adhesions, general septicæmia and mitral insufficiency.

## Miscellany.

### A FORM OF GINGIVITIS COMMON TO MEN AND DOGS IN INDIA.

SURGEON J. R. ROBERTS<sup>1</sup> of the Indian Medical Service describes a gingivitis which is often mistaken for a symptom of scurvy, but which has distinct characteristics of its own, and is entirely a local disease. It is characterized by a bright red velvety condition of the gums; its almost invariable limitation to the front of the mouth; the ulceration that surrounds the bases of the teeth, generally the incisors, which process in advanced cases continues to extend, destroying the alveolus and exposing the fangs, until the teeth remain but loosely attached or drop out; the tendency to hæmorrhage on pressure or the slightest injury; the occurrence of an exactly similar process in dogs, remarkably limited in them to incisors and canines, whereby their small front teeth are frequently lost; the acid reaction of the mouth and the fetid odor given off.

Microscopic examinations of scrapings show a large number of different micro-organisms. The disease is not limited to natives, but is common enough among British soldiers. Its worst effects are seen in a hot moist climate. The disease is essentially a slow chronic process. The treatment indicated is a light scraping of the ulcerations, touching them with strong carbolic acid or other antiseptic, and an alkaline mouth-wash.

### STERILIZATION OF NAIL-BRUSHES.

SPIELHAGEN<sup>2</sup> found that nail-brushes which lie on washstands with the soap, as they so often do, and also those which have been used for scrubbing hands and patients' skins, contain generally a large number of micro-organisms. The best and quickest method of disinfecting them is by boiling. Another thorough method is to keep them permanently in a solution of corrosive sublimate (1-2000). The author finds that those brushes which have wooden backs are not much injured by either process.

### IDIOCY AND THE OBSTETRIC FORCEPS.

A WORK has recently appeared, by Drs. Winkler and Bollaen, of Utrecht, entitled "Der Forceps als Ursache von Idiotismus."<sup>3</sup> They bring forward two cases to prove that the forceps may cause so much damage to the fetal cranium as to damage both its development and the substance of the encephalon itself, the result being idiocy. In the first case, symmetrical areas of damaged cortex were found on the surface of the hemispheres. The subject had been delivered by forceps, but no depressions on the calvaria were detected. Since the case occurred, ten brains of idiots were examined after death, and in two the same symmetrical affection of the cortex was found. The calvaria of no fewer than six of the subjects exhibited the characteristic depressions, and presumably most at least of these depressions were caused by forceps. The second of the two thoroughly investigated cases occurred in an

idiot dwarf, delivered by forceps; there were deep symmetrical depressions on the calvaria close to the sagittal suture. The history was well traced, for the patient died of old age at sixty; she had resided for forty years in the Utrecht Lunatic Asylum, and never could say more than two words. The cortex and deeper tissues were extensively diseased immediately under the cranial depressions. The entire encephalon weighed only 742 grammes. The authors wish it to be understood that they base no fanatical doctrines against the midwifery forceps on the strength of their researches. They go further, and note that it is known that the prolonged pressure of the maternal bony pelvis on the fetal head is certain to inflict damage, whilst the forceps carefully employed usually causes no injury of any kind to the child.

### TREATMENT OF THE NIGHT-SWEATS OF PHTHISIS.

HUCHARD reports in the *Rev. Gén. de Clin. et de Thérap.*, February 4th, the results with many medicaments tried for the relief of the sweating of phthisical patients.<sup>1</sup> Among these may be mentioned lead acetate, tannin, phosphate of lime, ergot, atropine, and muscarine. Of these the two first are unreliable, and are seldom used, and probably atropine sulphate is the most valuable (one-half to one milligramme at night). Phosphate of lime should be given in large doses (one to two drachms daily) to produce anhydrotic effects, and even in these doses it has several times failed. Ergot (fifteen to twenty-two grains of the powder at night) is much more reliable. When the sweats coexist with more or less marked fever, the author recommends the use of quinine combined with ergot.

R Quinine sulph. . . . . gr. xvi.  
Fulv. ergot . . . . . ʒ ss.

Divide into four cachets — two or three to be taken daily.

This formula is specially valuable in phthisis with hæmoptysis. Lastly, powdered agaric is an excellent remedy, not equal to atropine, but perfectly harmless, and never causing derangement of digestion. It may well be combined with tannin or belladonna, given in doses of three or four grains.

The same writer speaks very highly of antipyrin in the initial fever of tuberculous patients. The older drugs, quinine, tartar emetic, salicylic acid, all fail, or have but slight effect. It is specially in this *initial* fever that antipyrin is of great service. One must, however, distinguish between an *analgesic* and an *antipyretic* dose of the drug. To obtain the former effect, one would give a large dose (say fifteen to thirty grains) in a short time, but this must not be done if its best action as an antipyretic is desired. It is well for this purpose to use constantly decreasing doses (say sixteen grains, twelve grains, eight grains), taking care to divide them so that at no time during the twenty-four hours is the patient not under the influence of the drug. Used in this way, Huchard declares that antipyrin seems to have a *special* action on the tuberculous lesion, and to greatly retard or to arrest its progress.

Professor Combemale<sup>2</sup> has used telluride of sodium in phthisical and other sweating. It was first recommended by Neusser who gave one-third or two-thirds of a grain in pill once daily. Combemale gave

<sup>1</sup> Indian Medical Gazette, March, 1891.

<sup>2</sup> Centraltidn. f. d. ges. Therapie, April, 1891.

<sup>3</sup> British Medical Journal, March 28, 1891.

<sup>1</sup> London Medical Recorder, March, 1891.

<sup>2</sup> Bull. Gén. de Thérap., January 15th.

it up to nearly one grain per dose, and tried its effects in eleven cases. His conclusions are: It is a powerful anti-sulfuric; a dose of nearly one grain gives the best results; it gives rise to digestive troubles, and especially to a strong garlic odor in the breath. All the compounds of tellurium cause a very disagreeable odor in the breath, and this must always be a bar to their employment, as it is very persistent and disagreeable.

In addition to the list sulphonal has been used with success by a few reporters.

### PROFESSIONAL ASPIRATIONS.

The following extract is taken from Professor Da Costa's Valedictory Address with the above title, delivered April 15th, before the graduating class of Jefferson Medical College. It has an especial interest in connection with his subsequently announced resignation of his professorship.

"One more professional aspiration I may mention. It is one born of the best ambition, and I hope it will be that of many of you, — to become a teacher. If you do, you will be but carrying out one of the honorable traits of this College. She has a gratifying record as the Mother of eminent teachers, and claims with pride her distinguished sons on many faculties of the land. Great schools leave the impress of their teaching and the characteristics of their success; they have great traditions. If you lead a teacher's life, you must accept with it a teacher's duty. One of his duties is to hand down the best traditions of medical life, and to try to do that which in time will add to them. He will, then, not simply instruct; he will do more, he will educate. He must also foster investigation, and be himself an investigator. His love for learning must never weaken; when he ceases to be more than an elder student, he ceases to be fit to be a teacher.

"A teacher's work does not die with him. It lives long after, and may give great results. Voltaire says of Virgil that he was Homer's greatest achievement: Dante says Virgil's. In science, and in the teaching of science, we find the same. Medicine teems with instances. Boerhaave inspired Haller; Hunter, Jenner; Cullen, Rush; Bretonneau, Trousseau. Through his pupils a teacher lives; the man passes away, the teacher remains in his pupils and becomes part of them. What a thought, that they, the lenient judges of his endeavor, the pledges of his aspirations fulfilled, the subsisting signs of his responsibility, transmit his life. What a thought, that through them he may influence action for more than one generation; that from his impulse may spring what is far above himself. What a thought, that the teachers live with those they taught. . . .

"What a stimulus, then, all this is to him who has the aspiration to instruct. And when the hour comes that I shall lay down this robe of teaching, when the time arrives that I address you no more, there will always remain the thought: I say it in all humility — that I shall live in you. I shall be with you in your struggles, shall share with you your successes. At every bedside of distress, at every bedside of hope, we meet again. The teacher is inseparably joined to you, to all his pupils. Awful, ever-present responsibility, constant excitant to truthful, arduous effort; a of happy he who has been so guided that he has never forgotten his responsibility nor relaxed his exertion; that he has used God's gift of teaching for God's purposes.

"My friends, I must say no more. But I may not leave you without thanking you and your predecessors for the brief life of nineteen years, which has added so greatly to the brightness and pleasure of my life. May kindly feelings ever remain with you in the times that separate us, and may happiness and prosperity and every blessing, now and always, attend you."

### OBITUARY. JOSEPH LEIDY, M.D., LL.D.

Dr. JOSEPH LEIDY, the eminent naturalist, died in Philadelphia, April 30th, aged sixty-eight. He graduated from the medical department of the University of Pennsylvania in 1844. Except during the civil war, when he was surgeon in the Satterlee General Hospital, he did not practise medicine. In 1853 he occupied the chair of anatomy in the University of Pennsylvania. In 1871 he was called to the chair of natural history in Swarthmore College, and in 1884 became the director of the department of biology in the University of Pennsylvania. He obtained the Walker prize in 1880, from the Boston Society of Natural History and the Lyell medal from the Geological Society of London, for his contributions to paleontology, and received the degree of LL.D. from Harvard in 1886.

He published more than eight hundred papers on biological subjects, many of which were from specimens obtained on various surveys under the United States Government, and submitted to him for study and report. Many of his papers were issued by the Philadelphia Academy of Natural Sciences, of which he was the President, the Smithsonian Institution, and under the auspices of the National Government. He was a member of many scientific societies at home and abroad.

The following reference to the death of Leidy is from the pen of a Philadelphia correspondent, himself distinguished for many years as a medical teacher and writer:

"The University has met with an irreparable loss in the death of Dr. Leidy. Of the long line of its medical professors only one other so deeply impressed his individuality; that was Rush. He was as brilliant as the leader of the medical doctrine and practice of the first quarter of this century, as Leidy has been fruitful in solid scientific progress. The one was a conquering hero, the other a modest, steadfast builder of scientific facts. Dr. Leidy's brother, also a physician, died of pneumonia, while the elder was dying of contracted kidney and brain oppression."

### PRESCRIPTIONS.

**WINE LEMONADE.** — Dujardin-Beaumetz recommends a vinous lemonade to promote diuresis in typhoid and other fevers, and gives the following:<sup>1</sup>

R	Red wine	.....	O ss.
	Tartaric acid	.....	3 ij.
	Water	.....	O iss. M.

Laillez<sup>2</sup> recommends the following:

R	Syrup of citric acid	.....	3 ij.
	Red wine	.....	3 viij.
	Essence of lemon	.....	ii xv.
	Water	.....	O ij. M.

**CHRYSAROBIN FOR HEMORRHOIDS.** — Kossakowski<sup>3</sup> has used with success this remedy proposed by Unna. For external hemorrhoids this ointment is used:

R	Chrysarobin	.....	gr. viij.
	Iodoform	.....	gr. ij.
	Ext. belladonnae	.....	gr. vj.
	Petrolati	.....	3 iv. M.
	Ft. ung.		

For internal, a suppository:

R	Chrysarobin	.....	gr. j.
	Iodoform	.....	gr. 4.
	Ext. belladonnae	.....	gr. 8.
	Olei theobromae	.....	gr. xxx. M.
	For one suppository.		

**FOR GOUT OF THE GREAT TOE.** — The *Bulletin Medical* gives the following:

R	Collodion flex.	.....	53 3 iiss.
	Ether	.....	3 ij.
	Acid. salicylic	.....	3 ij.
	Morphine hydrochlor.	.....	gr. xxx. M.
	Sig. Paint on the toe every few hours.

## Correspondence.

## INFLUENZA IN EDINBURGH, IN THE OLDEN TIME.

BOSTON, April 29, 1891.

MR. EDITOR:—The following description of "the prevailing epidemic" in Edinburgh two hundred and thirty years ago may seem to you worth reprinting. It occurs in a letter from the English resident, Randolph, to the premier, dated November 30, 1562.

"Immediately upon the Queen's arrival here she fell acquainted with a new disease that is common in this town, called here the 'New Acquaintance,' which also passed through her whole household, sparing neither lord, lady nor damoiselle—not so much as either French or English. It is a pain in their heads that have it, and a soreness in their stomach, with a great cough; it remaineth with some longer, with other shorter time as it findeth apt bodies for the nature of the disease.

"The Queen kept her bed six days; there was no appearance of danger, nor many that die of the disease, except some old folk, etc."

The above is quoted from Miss Strickland's "Life of Mary Stuart." The Queen was at Holyrood.

Yours truly,

\* \* \*

## RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, APRIL 25, 1891.

Cities.	Estimated population for 1890.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from					
				Infectious diseases.	Acute lung diseases.	Diarrhoeal diseases.	Diphtheria and comp.	Scarlet fever.

Peabody . . . .	10,158	2	0	—	—	—	—	—	

Deaths reported 3,884; under five years of age 1,532; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fevers) 494; acute lung diseases 1,002; consumption 260; influenza 158; diarrhoeal diseases 102; diphtheria and croup 97; scarlet fever 87; typhoid fever 81; measles 45; cerebro-spinal meningitis 27; whooping-cough 23; erysipelas 17; malaria fever 3; small-pox 2. From typhoid fever Philadelphia 30, Chicago 26, Cincinnati and Washington 6 each, New York and Brooklyn 1 each.

2, Nashville, Worcester, Springfield, Chelsea and Haverhill 1 each. From measles New York 20, Chicago 12, Brooklyn 9, Washington, Nashville, Charleston and Quincy 1 each. From cerebro-spinal meningitis Chicago 16, New York 10, Washington 3, Philadelphia and Brooklyn 2 each, Boston, Cambridge and Salem 1 each. From whooping-cough New York 8, Brooklyn 5, Chicago 4, Boston 3, Philadelphia 2, Washington 1. From erysipelas New York, Brooklyn and Washington 3 each, Boston and Cambridge 2 each, Chicago, Philadelphia, Nashville and Salem 1 each. From malaria fever Brooklyn 2, Philadelphia 1. From small-pox New York and Philadelphia 1 each.

In the twenty-eight greater towns of England and Wales with an estimated population of 10,010,426, for the week ending April 18th, the death-rate was 22.5. Deaths reported 4,321; acute diseases of the respiratory organs (London) 804, measles 150, whooping-cough 141, diphtheria 42, diarrhoea 36, fever 27, scarlet fever 24.

The death-rates ranged from 16.7 in Wolverhampton to 33.9 in Sheffield, Birmingham 17.3, Bradford 18.2, Huddersfield 20.1, Leeds 23.9, Liverpool 21.9, London 20.5, Manchester 27.4, Newcastle-on-Tyne 31.6, Nottingham 21.7, Sunderland 26.3.

In Edinburgh 21.8, Glasgow 26.0, Dublin 27.5.

## METEOROLOGICAL RECORD.

For the week ending April 25, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

## OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM APRIL 23, 1891, TO MAY 1, 1891.

By direction of the Secretary of War, Lieutenant Colonel JAMES C. MCKEE, surgeon, having been found incapacitated for active service by an Army Retiring Board, is relieved from further duty as attending surgeon and examiner of recruits at Philadelphia, Pa., and will proceed to his home and report by letter to the Adjutant General of the Army. Par. 3, S. O. 96, A. G. O., Washington, April 28, 1891.

Leave of absence for twenty-one days, to take effect on or about May 1st next, is granted Captain GEORGE E. BURNELL, assistant surgeon United States Army, Camp Pilot Butte, Wyoming. Par. 3, S. O. 43, Department of the Platte, Omaha, Neb., April 26, 1891.

## OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MAY 2, 1891.

GEORGE A. LUNG, assistant surgeon, granted two months' leave of absence.

A. A. FLOEHLING, medical inspector, detached from Navy Yard, League Island, and waiting orders.

W. H. JONES, surgeon, ordered to Navy Yard, League Island.

O. D. NORTON, passed assistant surgeon, detached from Naval Hospital, Chelsea, Mass., and waiting orders.

F. J. B. CORDEIRO, passed assistant surgeon, ordered to Naval Hospital, Chelsea, Mass.

## MASSACHUSETTS VOLUNTEER MILITIA. BOARD OF MEDICAL OFFICERS.

There appeared before the Board this day (April 30, 1891), Major Charles W. Galloupe, of Lynn, who was duly examined and found qualified as surgeon, Eighth Regiment Infantry.

## SOCIETY NOTICES.

**BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.**—A regular meeting of the Society will be held on Monday, May 11, 1891, at the Medical Library, 19 Boylston Place, at 8 o'clock P. M.

Reader: Dr. H. C. Ernst, "Preliminary Report on the Clinical Use of Tuberculin."

All members of the Massachusetts Medical Society are invited to attend this meeting. Only members of the Boston Society for Medical Improvement are expected to take part in the discussion unless specially invited to do so.

G. G. SEARS, M.D., *Secretary*.

**NORFOLK DISTRICT MEDICAL SOCIETY.**—The annual meeting will be held at the Norfolk House, Eliot Square, Roxbury, Tuesday, May 12th, at 12 M.

Dinner. Annual Address, Francis H. Brown, M.D. Remarks by members.

The Board of Censors will meet at same place at 12.45 P. M.

The Examination of Candidates will take place one week later, on Tuesday, May 13th, at 7 P. M., at the office of Dr. J. C. D. Pigeon, 130 Warren Street, Roxbury. The written Examination will begin at 7 P. M., the oral at 8 P. M.

JAMES C. D. PIGEON, M.D., *Secretary*.

## APPOINTMENTS.

William M. Conant, M.D., and Charles L. Scudder, M.D., have been appointed surgeons to out-patients at the Massachusetts General Hospital.

## VIRCHOW TESTIMONIAL FUND.

Further contributions have been received by the Boston members of the American Committee, from the following physicians:

James C. White, Boston . . . . .	\$20.00
Francis P. Sprague, Boston . . . . .	10.00
Morrill Wyman, Cambridge . . . . .	5.00
Benjamin Cushing, Dorchester . . . . .	5.00
Joseph P. Oliver, Boston . . . . .	10.00
Maurice H. Richardson, Boston . . . . .	10.00
Edward Wigglesworth, Boston . . . . .	15.00
Vincent V. Bowditch, Boston . . . . .	2.00
Theodore F. Breck, Springfield . . . . .	5.00
Maurice D. Clarke, Haverhill . . . . .	5.00
Henry Jackson, Boston . . . . .	5.00
Elbridge G. Cutler, Boston . . . . .	5.00
George M. Garland, Boston . . . . .	5.00
Arthur H. Nichols, Boston . . . . .	5.00
James R. Chadwick, Boston . . . . .	5.00
John C. Irish, Lowell . . . . .	5.00
William F. Whitney, Boston . . . . .	10.00
Herbert L. Burrell, Boston . . . . .	10.00
Samuel J. Mixer, Boston . . . . .	10.00
Arthur T. Cabot, Boston . . . . .	10.00

## RALPH A. PARSONS, M.D.

At a special meeting of the Faculty of the Boston Dental College the following resolutions were passed:

"Whereas, in the dispensations of Divine Providence, a most highly esteemed and able instructor in this college, Dr. Ralph A. Parsons, has been removed by death, therefore:

"Be it resolved, that in the death of Dr. Parsons, the Boston Dental College has sustained the loss of an earnest and enthusiastic worker; one whose able scientific and practical instructions were shown in the remarkable progress of the students under his charge.

"It is therefore voted that a copy of these resolutions be spread upon the college records, in the leading medical and dental journals, and that a copy be also sent to his immediate relations."

GEORGE F. FANES, M.D., D.D.S.,  
*Committee for the Faculty.*

## OBITUARY. PHILIP LEIDY, M.D.

Dr. Philip Leidy died in Philadelphia, April 28th, aged fifty-three. He graduated from the medical department of the University of Pennsylvania in 1859. During the war he served as surgeon of the One Hundred and Sixth Regiment, Pennsylvania Volunteer, was post surgeon at Manchester and medical inspector of Shenandoah, Va., on the staff of General Sheridan. He was, *de facto*, physician in chief. He was the author of a number of reports to the medical and surgical departments of the United States Army, and made many contributions to medical literature. He was brother of Joseph Leidy, who survived him only twenty-four hours.

## OBITUARY. PAUL H. KRETZSCHMAR, M.D.

Dr. Paul H. Kretzschmar, Supervisor at Large of King's County, died at his residence in Brooklyn, on April 28th, of Bright's disease, aggravated by an attack of the grip. Dr. Kretzschmar was born in Dresden, in 1847, and graduated from the University of Berlin. He came to this country in 1863, and in 1872 opened a drug-store in Brooklyn. While engaged in that business he studied medicine, and in 1877 received the degree of M.D. from the Long Island College Hospital. He built up a lucrative practice, and in 1889 was elected Supervisor; in which position he has been active in securing many needed reforms in the county administration.

## DEATHS.

J. H. WARD, M.D., of Brooklyn, N. Y., died April 15th, aged sixty-seven.

RICHARD GUNDRY, M.D., Superintendent of the Maryland Hospital for the Insane, died April 23d, aged sixty-two.

JESSE P. BANCROFT, M.D., for twenty-five years Superintendent of the New Hampshire Asylum for the Insane, died in Concord, N. H., April 30th, aged seventy-five.

JOHN FREDERICK MAY, M.D., of Washington, D. C., died May 1st, aged seventy-eight.

## BOOKS AND PAMPHLETS RECEIVED.

Studies of Old Case-Books. By Sir James Paget, Bart. London: Longmans, Green & Co. 1891.

How Should Girls be Educated? Presidential Address by William Warren Potter, M.D. Reprint. 1891.

Taking Cold. By Frank H. Bosworth, M.D. Physicians' Leisure Library, etc. Detroit: George S. Davis. 1891.

Bacteriology and Preventive Medicine. By Stephen Smith Burt, A.M., M.D. New York: Stettiner, Lambert & Co. 1891.

Thirtieth Annual Report of the Cincinnati Hospital to the Mayor of Cincinnati, for the Fiscal year ending December 31, 1890.

Thirteenth Annual Report of the State Board of Health of Connecticut for the year ending November 30, 1890. New Haven. 1891.

Historical Sketch of the University of Maryland School of Medicine (1807-1890). By Eugene Fauntleroy Cordell, M.D. Baltimore: 1891.

Severe Puerperal Eclampsia. The Immediate Induction of Labor: Recovery. By William H. Morrison, M.D. Holmesburg, Pa. Reprint. 1891.

Practical Treatise on Electricity in Gynecology. By Egbert H. Grandin, M.D., and Josephus H. Gunting, M.D. Illustrated. New York: William Wood & Co. 1891.

Fever: Its Pathology and Treatment by Antipyretics. Boylston Prize Essay. By Hobart Amory Hare, M.D., B.Sc. Philadelphia and London: F. A. Davis. 1891.

Electricity, Its Application in Medicine and Surgery. By Wellington Adams, M.D. Two volumes. Detroit, Physicians' Leisure Library: George S. Davis. 1891.

The Diseases of Personality. By Th. Ribot, Professor of Psychology at the College de France. Authorized translation. Chicago: Open Court Publishing Co. 1891.

Die Schürungen und Entschuldigungsansprüche der Arbeiter. Von Dr. med. A. Moeren, Geh. Medicinal-Rath. Düsseldorf: Druck und Verlag von August Bagel. 1891.

Consideraciones Medico-Legales Acerca De La Muerte Por La Electricidad Industrial, por Eduardo F. Pla, M.D. Habana: Imprenta De A. Alvarez Y Compania. 1891.

Intra-Peritoneal Myo-Fibroma of the Rectum weighing twelve pounds, successfully removed by Laparotomy. By N. Senn, M.D., Ph.D., of Milwaukee, Wis. Reprint. 1891.

Early Diagnosis of some serious Diseases of the Nervous System: Its Importance and Feasibility. By E. C. Seguin, M.D. Boston: Dannel & Upham, Publishers. Reprint. 1891.

Medical Symbolism in Connection with Historical Studies in the Arts of Healing and Hygiene. Illustrated. By Thomas S. Szozinsky, M.D., Ph.D. Philadelphia and London: F. A. Davis. 1891.

Text-Book of Bacteriology. By Carl Fraenkel, M.D., Professor of Hygiene, University of Königsberg. Third edition. Translated by J. H. Lindsey, M.D. New York: William Wood & Co. 1891.

Surgery, A Practical Treatise with Special Reference to Treatment. By C. W. Mansell Moullin, M.A., M.D. Assisted by various writers on special subjects, with five hundred illustrations. Philadelphia: P. Blakiston, Son & Co. 1891.

## Original Articles.

### METHODS OF TEACHING ANATOMY AT THE HARVARD MEDICAL SCHOOL: ESPECIALLY CORROSION PREPARATIONS.<sup>1</sup>

BY THOMAS DWIGHT, M.D.,  
*Parkman Professor of Anatomy.*

THE idea of holding a meeting of the Academy in this building is to my mind a very happy one. It gives me the opportunity of speaking of our methods of anatomical instruction, and of displaying the treasures of our museum before an appreciative audience to whose knowledge they would hardly be brought otherwise. It is one of the greatest discouragements of those who labor to establish museums of a somewhat restricted nature, that it takes so many years for the merits of a collection to be known. Few visit our museum besides those belonging to the School.

My purpose to-night is to speak solely of methods of anatomical instruction, and I divide my remarks into two parts, separated by no very definite line. The first shall comprise what may be called the apparatus of instruction, used chiefly in the lecture-room; the other preparations which, though used more or less before the class, have also an intrinsic scientific worth and belong especially to the museum.

To begin with the former: Our collection of charts is a fine one. I have no time to dwell on it, but desire to show some of these diagrams of bones copied from Holden's *Osteology*, with red and blue lines marking the origin and insertion of muscles. They are most useful for teaching, and will have, I am sure, new interest to this audience, as they have an additional value to me, when it is known that they are the handiwork of my venerable predecessor, Dr. Holmes, made in the later years of his professorship. We have here a similar series on the bones themselves, painted by Dr. Newell, formerly an assistant in the Anatomical Department. These large, rather diagrammatic representations of parts of the skeleton, are used in transparent slates on which the soft parts, muscles, vessels, nerves, etc., may be rapidly sketched before the class.

Our collection of models is a very good, indeed, an exceptional, one. Besides the standard ones in papier-mâché which are seen everywhere, we have one in wood of some of the cranial bones and the bones of the face, made under the direction of Dr. Holmes, and we have these enlarged models of the bones made of blotting paper, by Mr. Emerton, subject to my criticisms, which for size, lightness and accuracy, are truly remarkable. These of the vertebrae are enlarged six times (linear measurement) and these others of the long bones and of the shoulder-girdle, three times. Here are the bones of the leg separate, and here joined by the interosseous membrane, which allows them to be shown as one apparatus, as they really are. Here are some of Cunningham's models showing the relation between skull and brain at different ages.

The development of the system of frozen sections as a means of teaching anatomy, has necessarily brought with it new models. We have many frozen sections in the school of which but few figure in the museum, owing to the difficulty and expense of satisfactory mounting. We have two large models in plaster, home-made, chiefly by Dr. Munro, one of the arm and one of the leg, which are cut into slices, the

surfaces of which are painted. From their large size they show more than the originals to a class, but we have the latter at hand for study and for small classes, as of graduates. We have also good models of sections through the body from Leipzig. This method of teaching anatomy by frozen sections is the growth of the last twenty-five years or so. It is longer than that since its use by Pyrogoff in Russia, and by Legendre in France, and not so long since I showed at Bowdoin College the first frozen sections made in New England, and probably in the United States.

Another method of instruction used occasionally in this department, chiefly to show the base of the skull and the general plan of the brain, is modelling in clay before the class. One need not be an artist to acquire with a little practice, skill enough to make models which convey ideas in a striking manner.

I come now to the second part of my subject, that of preparations, which though they may be brought before the class, have their home in the museum. In Europe the museum often gives a reputation to the school and there are preparations which are known among anatomists just as rare coins, precious stones, and works of art, are familiar to collectors who may never have seen them.

Our Warren Museum, founded by John C. Warren, has indeed a name among museums in this country; but owing to the labors of the late Professor J. B. S. Jackson, the pathological portion has so far outstripped the anatomical one proper as to have given the stamp to the museum. This is pretty clearly shown by the catalogue of the Warren Anatomical Museum, prepared by Dr. Jackson and published in 1870.

Eight years ago, almost the only series of preparations illustrating normal anatomy which could be shown with satisfaction, was a set of arterial dissections by Dr. R. M. Hodges. Though some thirty years old they still keep their value.

Our collection of frozen sections is large, but as I have said, comparatively few are on exhibition. As for the bones I say little, although there is a great deal to say. We have probably an unrivalled display of series of thin slices of bone to show the wondrous tracery of nature's architecture. Suffice it to say that we have sets of sections arranged in regular order showing the whole of the end of a bone cut in a certain direction, while other series show it cut at right angles to the plane of the former set. There are also series showing corresponding cuts of certain bones in man and in several animals.<sup>2</sup> We have also a collection to show anomalous structures in bones, and another, probably very nearly an unique one, to teach the range of individual variation and to further the study of the relation between the shape of the bones and the figure of the individual; but the time has not come to report on this subject. I cannot leave the department of osteology without alluding to the very valuable addition to our array of skulls, presented a few years ago by Dr. J. Collins Warren.

I desire, however, to speak particularly of our sets of corrosion preparations, especially as it is evident from the recent writings of one or two gentlemen who have busied themselves in this matter, that our collection is not widely known. A corrosion preparation is one in which the vessels, the ducts, or cavities of organs, as of the ear or heart, are filled by a fluid which will harden and so give the shape of the vessel or

<sup>1</sup> Read before the American Academy of Arts and Sciences, April 8, 1891, at the Harvard Medical School.

<sup>2</sup> See appendix.

cavity. After that the organ is corroded or digested so as to be completely destroyed, and all that remains is the cast of the cavity. Most beautiful and most instructive preparations are obtained in this manner. We have here corrosion preparations of three different kinds each of which has its own merits.

The first in order of making are these in brilliant colors by a method taught me by Professor Rüdinger of Munich, over twenty years ago, which differs from that of Hyrtl, with whose name these preparations are generally associated. The injecting mass is a mixture of rosin and white wax colored with paint dissolved in balsam of copaiba. After the injection the organ is destroyed by hydrochloric acid and water. When the injection alone is left it is given a gloss and greater strength by pouring over it repeatedly a solution of gelatine in acetic acid. The preparations are certainly beautiful, especially when several vessels are injected in different colors, as this kidney, with a red artery, a blue vein and a yellow ureter, and this liver with a yellow portal vein, a blue hepatic vein, a red artery, and a green bile duct.

Hyrtl in his work on corruptions relates that when Aslanian Pascha, a high medical official in the Ottoman army, visited his museum, surprise drew from the silent Turk the exclamation: "*Mais ce ne sont pas des préparations anatomiques, — ce sont des bijoux*," to which Hyrtl adds complacently, "And he was right." The chief objections to this method are the great difficulties in the process, in the course of which many more failures than successes occur, and the brittleness of the preparations. This last defect, however, is greatly exaggerated, for if the mass be originally of proper consistency a preparation with ordinary care will last for many years. The oldest of these is this kidney made in the autumn of 1883. Apart from the beauty of these preparations they have the merit that the trunks of large vessels are fully distended, that the mass reproduces sharply the shape of cavities, and that the relations of different parts are well shown.

The next kind of corrosion is that of Woods's fusible metal which consists of bismuth (7 parts), lead (1 part), tin (2 parts) and cadmium (1 part). This mass melts at a low temperature and can be injected merely by its weight, unless, perhaps, in the case of very fine vessels, without the use of a syringe. It runs if anything, finer than the preceding one. The tissues of the organ are destroyed by caustic potash. The cast which this mixture makes is a very good one. It has the great disadvantage that different vessels cannot be filled with different colors. It has another drawback which would not be anticipated; to wit, that owing to the weight the casts tend in the course of years to become distorted. This can be obviated to a great extent by a carefully conceived system of supports when the specimen is mounted. Among the best preparations of this kind are those of the labyrinth of the middle ear with the cavities of the temporal bone and of the pharynx with the neighboring cavities, and of the fetal circulation.

The third kind of corrosion is that of celloidin, which, like the preceding, was introduced into this School by Dr. Mixer, Demonstrator of Anatomy. The celloidin being cold, is injected slowly by repeated borings with a syringe of which the piston is driven by a screw. Wonderfully fine injections are obtained, and, of course, several different colors may

be used. The soft parts may be destroyed by acid; but Dr. Mixer has invented a digestive fluid which is better. Here is a truly admirable injection of the arteries of an entire leg and foot. The almost capillary net work at the balls of the toes is finely shown. Here, also, is a kidney in two colors, so completely injected that only the surface is visible. The deficiencies of this method, which in some respects gives the most perfect results, is that the large vessels are not distended, and that the preparations are preserved in fluid. I may say that all the celloidin preparations are by Dr. Mixer, and so are all the metallic ones with, I believe, one exception. The wax and rosin ones are, with a few exceptions, my own work.

Believing that one of the first duties of a professor of anatomy, apart from actual teaching, is the formation of an anatomical museum, I have devoted myself to that end. Whatever success has been gained is due in great measure to my assistants, both past and present, above all to Dr. S. J. Mixer, of whose skill and ingenuity the cases of the Warren Museum bear eloquent witness. It is a pleasure to me to acknowledge also the readiness of Dr. Whitney, the curator, to further our efforts to build up the part devoted to normal anatomy.

#### APPENDIX.

To this brief sketch of some parts of our Museum I wish to add a list of the preparations by the various methods of corrosion and of those of thin sections of bone, showing its internal structure.

#### CORROSION PREPARATIONS.

##### I. Wax and Rosin.

1. Liver, human; portal vein yellow, hepatic vein blue, hepatic artery red, bile duct green.
2. Liver of child; portal vein yellow, hepatic vein blue.
3. Liver of opossum; portal vein red, hepatic vein blue.
4. Lung, human (mounted upright showing all sides); pulmonary artery blue, pulmonary vein red.
5. Lung, human (showing outer surface); pulmonary artery blue, pulmonary vein red, bronchus yellow.
6. Ditto (showing inner surface); colors the same.
7. Both lungs of infant; colors the same.
8. Both lungs of opossum; artery red, vein blue.
9. Trachea and bronchial tubes of seal; yellow.
10. Heart and large pulmonary vessels of child; arterial system blue, venous red.
11. Kidney, human; artery red, vein blue, ureter yellow.
12. Kidney, human; artery red, vein blue.
13. Ditto.
14. Kidney, human; artery red, ureter yellow.
15. Kidney, human; vein blue, ureter yellow.
16. Kidney, human; artery red.
17. Kidney, human; pelvis yellow.
18. Kidney of seal; artery red, ureter yellow.
19. Both kidneys of seal with aorta and vena cava; arteries red, veins green. The plexus of large veins surrounding the kidney is shown.
20. Circle of Willis, human; red.
21. Placenta, human; arteries red, veins blue.
22. Penis, human; red. (Dr. Franklin Dexter.)

##### II. Fusible Metal.

1. Pulmonary artery, human.
2. Pulmonary veins, human.
3. Trachea and bronchial tubes, sheep.
4. Trachea and bronchial tubes, rabbit.
5. Cat's lung showing lobules and air cells.
6. Trachea and bronchial tubes (dog?).
7. Pulmonary vein, cat.
8. Nasal chambers, pharynx, antra and frontal sinuses of adult.
9. Ditto.
10. Ditto, with the cavity of the mouth and the larynx.
11. Nasal chambers, pharynx and mouth of child at term.
12. Heart and great vessels of infant about term.
13. Ditto.
14. The same, injected from the umbilical vein, showing nearly the whole of the characteristic part of the fetal circulation.

15. Ditto, without the heart.
16. The superior longitudinal sinus of adult.
17. The superior longitudinal, the straight, and lateral sinuses of a child.
18. Ditto.
19. Veins of vertebral column.
20. The internal ear and cavities of the temporal bone, human.
21. Two of the internal ear, human. (Dr. Franklin Dexter.)
22. Portal vein, human.
23. Ditto.
24. A branch of the hepatic vein of an ox.
25. Ditto, with a branch of the portal vein.
26. Small piece of portal vein (ox?).
27. Kidney, human, renal artery and vein.
28. Sheep's kidney, artery.
29. Sheep's kidney, vein.
30. Neck of bladder and large part of male urethra, human.
31. Neck of bladder and prostatic and membranous portions of urethra.
32. Neck of bladder and prostatic and membranous portions of urethra.
33. Female urethra, human.
34. Portion of corpora cavernosa of penis, human.
35. Ditto. N.B. The cavities in one are much larger than in the other.
36. Small portion of corpus spongiosum, human.
37. Glans penis, injected from dorsal vein, human.
38. Cavity of body of uterus, human.
39. Cavity of cervix of uterus, human.

### III. Celloidin.

1. Arteries of leg and foot, red.
2. Arteries of hand, red.
3. Ditto.
4. Ditto.
5. Arteries of forearm and hand of child, red.
6. Pancreas, human, injected through duct.
7. Vessels of a fold of jejunum and its mesentery, human; artery red, veins blue.
8. Vessels of small piece of jejunum, opened, showing the valvule conniventes, the same colors.
9. Veins of cecum of child, blue.
10. Both lungs of child, arteries blue, veins red.
11. Kidney, human, artery and vein, both red.
12. Kidney, monkey, artery red.
13. Kidney, cat, vein red.
14. Kidney, opossum, artery red, showing glomeruli.
15. Glans penis, human, injected from dorsal vein, red.
16. Uterus and appendages, human, veins blue, artery (of one side) red.
17. Placenta, human, arteries red, veins blue.

### SECTIONS OF BONE.<sup>3</sup>

1. Vertebral column; sagittal sections through vertebrae, striking the pedicles, from axis to last lumbar. 23.
2. Spine of shark; sagittal sections through four vertebrae in different planes. 4.
3. Lumbar vertebra, horizontal sections, one near middle, one near end. 2.
4. Sacrum; one sagittal section, one frontal. 2.
5. Vertebra of horse. 4.
6. Vertebra of lion. 3.
7. Transverse sections of vertebra of porpoise, alligator, python, manatee and seal. 7.
8. Transverse section of vertebra of cetacean.
9. Transverse section of vertebra of horse mackerel.
10. Scapula, through spine and glenoid cavity.
11. Frontal sections through head of humerus, of man, cetacean, dog and seal. 4.
12. Ditto of moose.
13. Ditto of mandril.
14. Ditto of Galapagos tortoise.
15. Frontal sections through head of humerus and upper end of femur, of chimpanzee, gorilla and lion. 6.
16. Ditto of bathebest. 2.
17. Cross sections through head of humerus. 6.
18. Cross sections through shaft of humerus. 11.
19. Cross sections through lower end of humerus. 12.
20. Frontal sections through lower end of humerus. 5.
21. Sagittal sections through upper end of ulna. 8.
22. Ditto of gorilla and lion. 2.
23. Oblique section lengthwise through lower end of ulna. 4.
24. Longitudinal section of metacarpal bone. 4.
25. Longitudinal section of radius and ulna. 2.
- 26-29. Four series of sections in different planes through innominate bone. 6, 6, 2, 17.
30. Frontal sections through upper end of femur. 5.
- 31-32. One series of sagittal sections through upper end of femur. 17, 14.
33. Flat sections through neck of femur. 5.

<sup>3</sup> These specimens are human unless it is otherwise stated. The figures at the end of each line denote the number of sections mounted on the tablet.

- 34-38. One series of horizontal sections of femur from about middle of head to knee. Those of the shaft are thick. 16, 16, 19, 18, 13.
- 39-40. One series of sagittal sections of lower end of femur. 14, 14.
41. A series of frontal sections of the same. 10.
42. Sagittal sections of patella. 16.
43. Frontal sections of patella. 6.
44. Horizontal sections of patella. 14.
45. Upper end of tibia, frontal. 13.
46. Ditto, sagittal. 15.
- 47-49. One series of horizontal sections of tibia, from the top to ankle-joint. Those of the shaft are thick. 9, 19, 11.
50. Lower end of tibia, frontal sections. 9.
51. Ditto, sagittal. 8.
52. Fibula, longitudinal sections from two bones. 2.
53. Astragalus, sagittal sections. 6.
54. Calcaneum, sagittal sections. 6.
55. Calcaneum, frontal sections. 18.
56. Calcaneum, sagittal sections, of chimpanzee, bear, lion and seal. 4.

## ALBUMINURIA: ETIOLOGY AND PROGNOSIS.<sup>1</sup>

BY HENRY JACKSON, M.D.

ALBUMEN may be present in the urine in several different forms; the most common form is serum albumen, and with this is often found another form, globulin. Both are detected by the usual chemical tests for albumen, and globulin does not occur independently of serum albumen. Peptones are found in the urine where there has been long-continued suppuration, or where the products of suppuration have been broken up and absorbed. For instance, peptones may be found in the urine in the third stage of acute lobar pneumonia, in empyema or in any case of suppuration of long duration.

Albumose, a compound form of albumen, which in its chemical characteristics stands between the proteids and peptones, is rarely met with. It has been found in cases of osteo-malacia, but as yet no important clinical or pathological significance has been attached to the presence of this form of albumen in urine.

Practically serum albumen is the only form whose presence is sought for in urine or from which we can draw conclusions of definite value as to the existence of a pathological process. Minute traces of albumen may undoubtedly be occasionally found in the urine of persons in perfect health where no cause can be ascertained for its existence; secondly, albumen occasionally appears in the urine of healthy persons after excessive exercise or the injection of large amounts of highly albuminous food.

Thomas Grainger Stewart, in an interesting monograph on albuminuria, devotes a chapter to the study of this symptom as it appears in people supposed to be healthy. He states that he found traces of albumen in such cases in a proportion of sixteen to thirty per cent. He reports no microscopic examination of the urine in these cases, but says that they presented no evidence of renal disease. He also quotes statistics similar in character from German, French and American writers. Stewart found that the proportion of cases of albuminuria was very much increased by violent or fatiguing exercise. In soldiers after a long march, albumen was found in sixteen to twenty-nine per cent. of all cases examined; many similar cases are given. He goes so far as to say, "The existence of albuminuria is not of itself a sufficient ground for the rejection of a proposal for life insurance." Stewart

<sup>1</sup> Read before the Boston Society for Medical Improvement, February 23, 1891.

art employs the usual chemical reagents employed for the detection of albumen.

My experience differs entirely from that of Stewart. As assistant to Dr. Wood I had the opportunity of making a large number of analyses; and during the last few years I have examined a large number of specimens of urine from cases of all sorts, as met with in private practice. Yet I have never met with a single case of albuminuria in which a microscopical examination did not disclose some pathological condition of the kidney or uropoietic system sufficient to account for the presence of the albumen. I have seen cases of albuminuria with secretion of a large amount of water where a single examination was negative, but repeated examinations have invariably discovered some pathological condition, as evidenced by the presence of casts or other pathological elements. Von Jaksch says, "A considerable amount of albumen is never found in the urine under normal conditions. Its appearance is always to be considered as an important pathological condition."

Certainly persistent albuminuria always points to some pathological lesion; and the results of my analyses convince me that transitory albuminuria is dependent upon some actual disturbance of the kidney substance, unless the albuminuria be of the kind usually spoken of as accidental.

*Tests for Albumen.*—The most delicate test for albumen which it is practical to use is the coagulation of the albumen by acidification with acetic acid, and the application of heat. This test is subject to two sources of error: first, if sufficient acid is not added, phosphates may be precipitated, which simulate exactly coagulated albumen; second, if too much acid is added and the urine be boiled, a soluble acid albumen may be formed. The test, with ferrocyanide of potassium is exact and easily performed in the office; the specimen of urine is made strongly acid by the addition of acetic acid, and then a few drops of a ten per cent. solution of ferrocyanide of potassium are added. If albumen be present a slight cloud appears in a few seconds, or if the albumen be abundant, a flocculent sediment is formed. There are two objections to this test: first, if the urine be rich in uric acid, the primary acidification with acetic acid may cause at once an abundant precipitate of urates; second, if there be a large amount of mucin present, a cloudiness is caused by the ferrocyanide due to the coagulation of the mucin. Nitric acid is a most valuable test, as by this means it is possible to demonstrate a very small amount of albumen unless urates are present. A precipitate may also be caused if the patient is taking any medicine of the balsam class, as copaiba, etc.

Direct experiment has shown that acidification and heat will demonstrate a smaller amount of albumen than nitric acid in the cold. Also the value of this test is not interfered with by the presence of urates or any drugs that I know of.

I wish this evening to present to the Society a short history of a few cases of albuminuria as illustrative of the various pathological lesions which may give rise to this important chemical symptom. I am indebted to Dr. C. P. Putnam for the clinical notes of most of the cases reported. Some cases of albuminuria, dependent upon simple and uncomplicated cystitis have come to my notice; but the cases which I report are all dependent upon some lesions of the kidney, as demonstrated by the presence of renal casts in the sedi-

ment. I present several cases as typical examples of the classes to which they belong. Some of my cases are of considerable interest in that in their etiology or clinical symptoms they differ markedly from the general laws laid down in the text-books.

#### ALBUMINURIA DEPENDENT UPON ACUTE NEPHRITIS.

**CASE I.** A girl, seven years of age. Previous health good in all respects. The child was much exposed to cold, and to all the injurious influences of bad hygienic surroundings, with scanty diet. Had a sudden attack of fever; a little vomiting; general oedema.

January 1, 1889. Urine was brownish red; specific gravity 1.030; albumen, one-half per cent; casts very numerous, especially fibrinous casts. Granular, epithelial and blood casts; free blood and brown granular detritus.

A week later there was a marked improvement in the general symptoms. The urine was more abundant; the albumen still one-half per cent; and in the sediment some fatty elements had appeared, replacing the blood found in a previous examination.

From this time there was a rapid improvement in all respects; and after six weeks no symptoms of the severe illness were to be found.

**CASE II.** Acute nephritis following scarlet fever. A boy, nine years of age, had scarlet fever of a mild grade. Three weeks later the urine became scanty and showed all the characteristics of acute nephritis. After one week the urine became very scanty and late in the afternoon the child became somnolent, soon perfectly unconscious. In my absence another physician was called who made a diagnosis of opium poisoning and ordered treatment accordingly. During the evening the child had convulsive movements of the right side of the face, the right arm and right leg. When the child was spoken to loudly he roused partially and counted slowly 26-27-28-29-30. He always counted as stated and did not speak. On the following morning he was perfectly conscious, had no symptoms of cerebral lesion, and from this time on made a rapid recovery. One month later he was perfectly well, and has remained so since. This case is of interest as demonstrating that distinctly localized symptoms as unilateral convulsion and aphasia may be dependent upon uremia.

#### CHRONIC NEPHRITIS.

Pathologically, chronic nephritis may be dependent upon two independent changes in the substance of the kidney,—the one a fatty degeneration of the parenchyma; the other, an interstitial nephritis. Anatomically, fatty degeneration uncomplicated by interstitial inflammation of greater or less degree, is almost unknown, except as the result of some poisoning, as arsenic, and so forth. So, clinically, it is difficult to make an accurate diagnosis as to the anatomical condition of the kidney. So far as we can judge from an examination of the urine an interstitial nephritis may exist as such from the beginning of the disease, or the primary disease may be a fatty degeneration of the parenchyma and gradually assume the form of a typical interstitial nephritis.

**CASE 3.** A lady, sixty years of age. In the summer of 1888 she had a hemorrhage in the retina, etc. Urine showed the presence of albumen and casts. The history at the time suggested that the disease had

already existed for a considerable time. There has been no œdema; vomiting has not occurred; there has been occasional headache. Her general health has been good; her chief complaint has been a general "tired feeling." There has been no disturbance of the heart; no enlargement, no murmur.

In November, 1888, examination of the urine was as follows: color, pale; specific gravity, 1,013; albumen, small trace; sediment contained numerous hyaline and fine granular casts.

Since then repeated examination of the urine has shown no material change. The amount of urine is large, the urea relatively considerably diminished. Last examination of urine normal.

**CASE II.** Boy, fourteen years of age. As a child he had pertussis, varicella, measles, and at three years of age a severe attack of tonsillitis. In the autumn of 1888, when he was twelve years old, he had an acute feverish attack ushered in by chills; for several days high fever, and subsequently moderate fever for four weeks; chief symptoms, diarrhœa and weakness; no vomiting, no œdema. At this time the urine contained much blood, was scanty, and the sediment was characteristic of acute nephritis. This acute attack occurred in October, 1888. In November, examination of the urine showed the following: color, yellow; specific gravity, 1,022; albumen, a large trace; urea increased; sediment, numerous hyaline and fine granular casts; a good many blood casts; little free blood. At this time he was rather pale, did not feel strong, but had a good appetite.

A month later the blood casts had disappeared from the urine, though the sediment still contained a good many red blood globules. Hyaline and granular casts in abundance. There had been a great improvement in his general health.

In January, 1889, many of the casts contained fat drops; the albumen was still small in amount. In May, 1889, his mother said that in all respects he seemed perfectly well; no œdema. Examination of the urine gave the following result: color, pale; specific gravity, 1,015; albumen, large trace; sediment, numerous red blood globules. Hyaline and fine granular casts; a few fat drops on some of the casts. Urea, twenty grammes to litre. During the last year the amount of albumen has increased to about one-fourth per cent.; the urea has never been less than twenty grammes to the litre; the sediment always contains numerous hyaline and granular casts, and in many of the casts fat drops are found.

The boy's general health has been perfectly good. No symptoms, except the physical examination of the urine have pointed to the presence of any renal disease. He is small in stature, but for a boy of his age is a good athlete. The fat casts point to some fatty degeneration of the parenchyma, but the case is of especial interest as the clinical history does not give a single clue to the existence of a disease which is usually considered so severe as a chronic parenchymatous nephritis.

Recently it has been discovered that the urine contains a small amount of arsenic, and it is possible that the elimination of this poison from the system may lead to permanent recovery.

**CASE III.** A lady of thirty-five. Though she had at the time no symptoms of renal disease, it was accidentally discovered that nephritis existed. Examination of urine: pale; specific gravity, 1,010; albumen,

small trace; urea small in amount; the sediment contained a few hyaline and fine granular casts.

I know no details of the further history of this case as the lady removed to the country, but she died within a year after the renal disease was discovered.

I have observed an interesting series of cases of albuminuria in connection with disease of the heart due to dilatation of the heart, dependent either upon fatty degeneration without valvular lesion, or upon uncompensated valvular lesion. In these cases the albuminuria is probably not due primarily to increased pressure in the venous system, but to some change of the parenchyma of the kidney. My reasons for this statement are that in the first place microscopical examination of the sediment has always shown the existence of casts, and, secondly, that physiological experiment has shown that in filtering an albuminous fluid through an animal membrane increase of the pressure does not cause an increase of the amount of albumen in the filtrate.

**CASE I.** Lady, forty years of age. Aortic regurgitation and obstruction. She first consulted a physician in June, 1887. At that time she complained of "flushing" and palpitation on exertion. These symptoms she had noticed only a short time and previously had considered herself well. Pulse intermittent, double murmur over aortic valve. Apex in sixth interspace outside of nipple. Area of cardiac dullness increased.

Examination of urine, June 12, 1887: Color yellow; specific gravity, 1,027; trace of albumen; two per cent. of sugar; in sediment a few red blood globules, no casts. July 20, 1887: A few casts in sediment; no sugar. During the summer she lived on an unrestricted diet; and in October, 1887, the urine contained eleven per cent. of sugar, and in the sediment a few, pure, hyaline casts.

Since that time the amount of sugar has varied in amount, according to the care with which she has adhered to a strict diabetic diet. The albumen has not disappeared, and the sediment has usually shown a few fine hyaline casts. The albumen and casts have not varied with the amount of sugar present.

Her general health has been good, in fact, far better than one would expect to find it in one who had the valvular lesion of the heart alone. Occasional examination of the amount of urea has shown it to be normal or increased in amount; namely, on one occasion forty grammes to the litre. The amount of urine has never been exceedingly large.

**CASE II.** A lady, sixty years of age. Health good until November, 1890. She then complained of feeling weak. She had some difficulty in breathing on exertion. The heart was weak. Under rest marked improvement.

Examination of urine November 23, 1890: Color yellow; specific gravity, 1,025; small trace of albumen; in sediment a few small hyaline casts; urea and uric acid increased. A month later, after rest and cardiac stimulants, no albumen, no casts.

January 22, 1891, an attack of severe headache; and on the following day a few casts were found in the sediment, but no albumen was detected.

**CASE III.** A man, seventy years old. Had been exceptionally well and strong up to November, 1888. In November he had feelings of oppression in the chest, with some pain. The heart was found to be dilated, weak and occasionally intermittent. A few

days later he had a sudden attack of angina pectoris from which he made a slow recovery.

Urine high color; specific gravity 1.018; very small trace of albumen; in the sediment a few hyaline casts were found.

Since November, 1888, there have been no severe attacks of angina. The action of the heart is very irregular, at times intermittent. In the spring of 1889, the albumen and casts disappeared from the urine. During the last year there has been slight albuminuria, dependent upon cystitis secondary to an enlargement of the prostate.

He has never been able to lead an active life, although for some time he could walk out, and now can drive.

I have observed several cases of albuminuria with the appearance of casts in the sediment associated with acute febrile attacks, namely, pneumonia, severe tonsillitis, typhoid, etc. In these cases there was always complete recovery within a few days or weeks subsequent to the subsidence of the fever. The anatomical basis for such cases of transient albuminuria is undoubtedly to be found in the pathological lesion described as granular degeneration or by the more general name "cloudy swelling." Three cases were associated with pregnancy in the last few months.

CASE I. Young primipara. No symptoms suggestive of renal disease. Three weeks before delivery the urine was yellow; specific gravity 1.021; small trace of albumen; in the sediment a few hyaline and fine granular casts. The albumen soon became more abundant, otherwise no bad symptoms.

Three days before delivery the urine was smoky in color, one-half per cent. of albumen; specific gravity 1.022. Amount not diminished. In sediment very numerous hyaline and fine granular casts; some blood. A little fat on a few of the casts.

Five days after delivery the urine contained only a small trace of albumen, and in the sediment no casts were found.

In a subsequent pregnancy, two years later, the urine was not abnormal in any respect.

CASE II. Second pregnancy. Slight oedema, otherwise no renal symptoms. Urine was yellow in color; albumen, one-fourth per cent.; in sediment a few fine granular casts. In this case the albuminuria and casts continued for several weeks after delivery. No impairment of general health in any way. In her first and third pregnancies the urine was normal in all respects.

CASE III. Again no renal symptoms, though the urine contained one-fourth per cent. of albumen and numerous casts. In all these cases the urine was normal in amount, and the urea, when tested, was normal or increased in amount.

Finally, I will briefly mention a few miscellaneous cases.

CASE I. A gentleman past middle life first noticed that he had to pass water very frequently. General health not robust. He took but little exercise. Heart not abnormal.

Urine rather pale; specific gravity, 1.016; small trace of albumen; in the sediment numerous crystals of calcium oxalate and a few hyaline casts. Urine increased in amount; urea normal. The oxaluria and casts lasted four weeks and then disappeared. No cause for the albuminuria could be discovered except

the oxaluria. The frequency of micturition disappeared with the other symptoms noted.

CASE II. A man apparently in perfect health, had two years ago a sharp attack of renal colic. During the attack the urine contained a small amount of albumen and numerous casts; also numerous epithelial cells similar to those found in the pelvis of the kidney. No return of renal colic or albuminuria.

CASE III. Young man, twenty years old. Until the spring of 1889 had always considered himself well. During the summer he found that he was easily tired. In September, 1889, examination of the urine showed one-fourth per cent. of albumen; in the sediment a good many hyaline and granular casts; a few blood globules. He had no headache or vomiting, no oedema; color good. No enlargement or other change of the heart.

In November, 1889, the examination of the urine was practically the same except that some of the casts contained fat, and a few fatty degenerated epithelial cells were found.

During January and February, 1890, he was in the South; and a specimen of urine received February 13th, showed an absence of casts; a very small trace of albumen. On his return in the spring of 1890 the urine again contained albumen and casts. In July, 1890, arsenic was found in the urine; and examination of the wall paper of his bedroom showed that it contained a good deal of arsenic. This winter he has passed in Asheville, and the last examination of the urine, made in December, 1890, showed a very small amount of albumen and an occasional cast.

In the absence of any symptoms pointing to nephritis, except the examination of the urine, and the marked improvement when he was away from home, I think it is reasonable to suppose that the albuminuria and casts may have been due to fatty degeneration, the result of arsenic.

As in cases of heart disease, we base our prognosis on the condition of the muscular tissue of the heart walls and the rate and rhythm of the pulse, and not upon the murmur heard, so in cases of kidney disease we can only judge of the real condition of our patient by knowing the amount of urea and water excreted, which informs us of the actual power of the kidney to perform its work.

I think I have shown that renal albuminuria may be due to many distinct lesions, and I wish especially to draw the attention of the Society to the two cases of chronic albuminuria with casts, in which arsenic was found in the urine.

## AN EPIDEMIC OF INFLUENZA.

BY S. G. WURFEL, M.D.,  
Superintendent Adams Nervine Asylum.

DURING the latter part of March an epidemic of the grippé began at the Adams Nervine Asylum. Several features of the disease were different from any which I saw a year ago, and as being peculiar, seem to me to deserve notice.

Between March 18th and 30th, twenty-eight cases occurred. This was a period of dull, rainy and damp weather. There was then a change and we had a few days of sunshine, during which no new cases appeared. Then a day or two before a storm there were more

cases, and in four days they numbered eleven. One case preceded March 18th, and its nature was not recognized until other cases occurred later.

Several of the patients were so slightly affected that they were not obliged to give up, and it is possible that one or two cases may have escaped notice. Forty persons are known to have been affected. Twenty-seven were confined to their beds from half a day to ten days. Four of five among the nurses continued at work, though with much discomfort, and only by great exertion of will. Only sixteen can be said to have had the disease severely.

The first symptoms were generally, pain in head and back, with lassitude, often aching of the limbs. Sometimes the patient said she felt as if she had caught a severe cold.

About the same time with the above pains and aches, sometimes as the first noticeable symptom, the throat became sore. This was present in almost every case. There were only one or two cases without the sore throat. In thirteen patients this symptom was not severe, and closely resembled an ordinary sore throat. In only a few of these thirteen were the tonsils enlarged.

In the other twenty-seven cases the tonsils were enlarged, the follicles inflamed and filled with secretions. In some cases the white patches were very large covering half or more of a tonsil.

In many cases the soft palate was dotted over with bright red points or pimples, and later when the soft palate was uniformly red, this was of a very dark shade. In a few cases instead of the follicles being especially affected, the fauces as a whole, including the tonsils, the pillars, the soft palate and the posterior wall, was of a dark port-wine color.

In eleven cases the tonsils were very much swollen so as to interfere with deglutition, not only by the pain, but by their size. In such cases the voice had a nasal tone, and in a few cases this tone was noticeable where the tonsils were not very large, or it appeared a few days later when the swelling was subsiding, as if due to a weakness of the muscles.

In only one case was there an abscess found in the tonsil, and that appeared after the disease had nearly run its course, the initial tonsillitis had subsided, and was probably due to imprudence in exposure to draughts of air.

Another early and constant symptom was the fever, the temperature rose rapidly, within a few hours to 102° or higher. In one case at 6 p. m., the temperature was 99.8°; at 9 p. m. it was 101.8°. The highest temperature noticed was 103.8°. Within twenty-four or thirty-six hours of the onset, the temperature reached the highest point, then gradually it dropped. If the general affection was not severe the temperature fell quickly. If the other symptoms continued, the temperature remained between 100° and 102° for a few days, then dropped to normal. The pulse was rather rapid, 120 or more; sometimes lacked in strength. When the temperature subsided, the pulse usually fell to about 100.

Less constant than the symptoms already mentioned was coryza. This was noticed in many cases a few days after the beginning of the disease. It could scarcely be called an initial symptom.

Nine of the patients had an eruption, varying from a slight erythematous redness, affecting only the face, to a general eruption, affecting the body and limbs.

This did not appear before the fourth day, and was in some cases delayed a week. It resembled measles very closely, and was followed by enfoliation of the cuticle; in the severest cases the skin peeling off in large flakes.

An eruption of herpes on the lips was noticed in five or six cases. In two cases this was quite extensive.

Among later and rarer symptoms may be mentioned nausea and vomiting, in only a few, but in some very persistent and troublesome; cough, persisting through several days, in a larger number; oppression across the chest, in three or four.

More general later symptoms were weakness, continuing several days or weeks, but less extreme than a year ago; aching of the back and limbs continuing for many days after the other symptoms, except weakness, had ceased.

The lighter cases required but little treatment. The severer cases were relieved of pain and aching by phenacetin in ten or twenty grains. Throats were sprayed with a solution of iodoform in ether, which caused considerable smarting and irritation at first, but soothed the discomfort later. A gargle of chlorate of potassa or alum also gave relief to the throat, and was especially grateful after the tonsillitis had subsided. For general treatment it was simply necessary to sustain the patient's strength. Anointing with oil was used to relieve the annoyance caused by the eruption, but was not of much benefit.

## Clinical Department.

### CASE OF ACUTE LOCAL OEDEMA COMPLICATED WITH PURPURA AND SALIVATION.

REPORTED BY WALTER H. HOLMES, M.D., WATERBURY, CONN.

A CASE of that singular disease, acute local oedema, similar to those reported by Dr. Robert W. Lovett of Boston, in the JOURNAL of October 30, 1890, occurred lately in my practice, and, in view of the rarity and ill-understood nature of the disease, seems worth reporting.

Edward Gunning, a laborer, who up to that time had been in excellent health, was taken on April 1, 1891, with a sudden painless swelling of his left great toe, which was of a dark red color. Thirty-six hours later his whole left foot swelled to a little above the ankle and was swollen for five days.

I saw him on April 8th, by which time the swelling in his foot and ankle had completely subsided. There was then a swelling over the middle of the right ulna, sharply circumscribed, about the size of half a hen's egg. The left forearm was swollen to the elbow. These swellings had the color of the normal skin, were painless and would pit somewhat on pressure, the depression however, quickly filling up again. The next day both hands were swollen, the right arm to a little above the elbow, and there were many purpuric spots on the flexor sides of both elbows. Both lower extremities on the second day were covered with purpuric spots, varying from the size of the end of a finger to that of a silver dollar. There was at no time any blood in the urine nor any hæmoptysis. Both arms were bandaged singly with flannel bandages cut on the bias. The arms were swollen for not more than two days, but the left hand for three.

As the disease seemed to have some resemblance to urticaria because of the sudden appearance and quick disappearance of the oedematous swellings, the patient was four days put upon an alkaline treatment, one ounce of citrate of potash in lemonade daily, but it had no effect on the course of the disease.

On the 10th and 11th there was profuse salivation, more than a quart being expectorated in a day. This salivation was doubtless due to the condition of the throat, the soft palate and uvula being swollen to three or four times their usual size, and both they and the posterior wall of the pharynx were of a dusky red color. One-sixtieth of a grain of atropine sulphate was given on the evening of the 11th, and checked the salivation in an hour; it did not again recur.

On the 13th the throat was well, and there was no swelling in the arms, but on each side of the abdomen there were large and considerably swollen patches which went down in a day under bandages. All these swellings were not of the skin only, but extended well down into the subcutaneous tissues.

On the 14th the right eye was closed, the lids being swollen many times their natural size. The next day the swelling was nearly gone from the right eye, but the left one was closed and the oedema extended over the greater part of the forehead and three or four inches into the hairy scalp. The forehead and scalp were quite tender on pressure. Otherwise, with the exception of the back, the disease was wholly painless and the patient hardly felt sick, though his tongue was coated and he had no appetite.

On the 19th and 20th, there was swelling of the back from the hips to the scapula; and it pained him to straighten his back. After this there was no more swelling, and the patient, apart from weakness from not having eaten anything, was quite well. The purpuric spots faded away in five days more. There was no itching during his illness. The only time that there seemed to be any occasion for anxiety, was during the swelling of the throat; but fortunately there was no oedema of the larynx. The only symptom the patient now complains of is a little tenderness of his feet, but he expects to be able to work again in a day or two.

The nature of these curious attacks has been considered to bear some relation to those of urticaria, and in some cases to have something to do with rheumatism. This patient never had rheumatism, nor was there anything resembling it during his illness. Though no one swelling lasted nearly as long as the first one in Dr. Lovett's paper — four weeks — still all together, one attack succeeding another, the patient was ill for three weeks.

## Reports of Societies.

### BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

REGULAR Meeting, Monday, February 23, 1891, the President, DR. FREDERICK I. KNIGHT, in the chair.

#### PATHOLOGICAL SPECIMENS.

DR. J. ORRIS GREEN showed a series of osseous preparations illustrative of diseases of the ear, chiefly the results of suppuration of the tympanum. They comprised specimens of carious ossicles, sequestra of the labyrinth, and various forms of mastoid disease, more

especially showing the different degrees of osteo-sclerosis and the important bearing this has on mastoid operations.

DR. H. JACKSON presented a paper on

#### ALBUMINURIA, ITS ETIOLOGY AND PROGNOSIS.<sup>1</sup>

DR. C. P. PUTNAM: All these cases have been either under Dr. Jackson's care or my own during the last few years, and it seems to me they are rather striking examples of the now pretty well-known fact that albuminuria and casts are to be regarded in a very different way from what they used to be. Not so very many years ago albuminuria and casts were considered the end of hope, but now it is by no means so. If I remember rightly, of those cases which have been mentioned by Dr. Jackson only one has died. The others are now living, and almost all of them in what may be called practically sound health. They are also examples of the fact which has been observed, that patients may have these signs of organic disease of the kidney without knowing anything about it. Perhaps they may suffer from general weakness, but not from any other symptoms of any kind. The boy whom Dr. Jackson referred to, in whom the disease was discovered about two years ago after an acute attack of nephritis, may perhaps have had it before that time, though there was not any sign of it at all. He had been out of town in the summer, made a visit to his grandfather in the fall, and then went to another grandfather in another town, and there was suddenly taken ill after a ride on a bicycle; but he was in the habit of riding. He had an attack of acute nephritis which did not cause any oedema, and some other severe symptoms were wanting. Since that time he has had a chronic affection of the kidneys, and in spite of this is playing in tennis matches and base-ball matches, from which he could only be restrained by main force.

I think the lady Dr. Jackson mentioned as having aortic murmurs and diabetes is an interesting case. At the time she applied to me she did not think of disease of any particular organ. She supposed there was something the matter with her skin, as her skin was burning hot whenever she made any exertion.

There are two cases where arsenic was associated, and though in neither of these can it be proved that arsenic was the cause of the trouble, I cannot help believing that it did in one case, that of a young man in college who had never been in the habit of taking any very violent exercise, was of good habits and rather studious. He spent the summer pleasantly in the mountains, and was not aware of any means by which he could have got such a disease as this, which came on very gradually with feelings of malaise. It was found that the papers he had had in his rooms in college were highly arsenical, and the rooms where he had been living since then were somewhat arsenical. The exposure was less than before, but he still had some arsenic in his urine. He has been improving, and seems likely to get well.

DR. WOOD: I have been very much interested in Dr. Jackson's paper and the cases which he has reported, and, so far as my experience has gone in the last fifteen or twenty years, it seems to me that anything which will either irritate the kidney, or any disease which will disturb the circulation of the kidney, is sure to produce albuminuria and casts; and anything which irritates the kidney, if that irritation continues

<sup>1</sup> See page 477.

any length of time, makes to a certain extent certain fatty changes which are perceptible by the examination of the urinary sediment. You find fatty renal cells, oil globules and fatty cells on some of the casts, and that explains the condition which exists in all cases of arsenical poisoning or any other form of irritant acting upon the kidney, or any other condition which produces irritation of the kidney for any length of time. If the irritation is continued for any length of time we are sure to find albuminuria with hyaline and granular casts and casts which have cells more or less fatty adherent to them, and of course a certain number of free oil globules adherent to the casts and free fatty renal cells. I have under observation now a case in which that condition of things exists, owing to heart disease due to seven or eight attacks of acute rheumatism during eighteen years, that is, I have followed up the case eighteen years. The man is apparently in as good condition as at that time, although albuminuria and casts have been constantly present. In long-continued cases of arsenical poisoning the same condition of things obtains. In diabetes, where there is a large percentage of sugar, there is always more or less albuminuria and casts, and I do not think that in case of diabetes the renal disease is at all important so far as any prognosis is concerned. There are some cases where there is both organic renal disease, that is, regular Bright's disease, and diabetes at the same time; but it is very rare that we have the two together. The diabetes may continue a good many years without producing such organic disease, but at the same time in any case of diabetes where there is seven or eight per cent. of sugar there is always a trace of albumen with hyaline and finely granular casts. If the sugar can be made to disappear the albuminuria and casts disappear.

The albuminuria due to simple disturbance of the circulation, which is very common in youth, is a very important matter; and the amount of albumen in some of the cases which I have had the opportunity of examining has reached as high as one-tenth or one-eighth per cent., and accompanied with hyaline and finely granular casts. Upon following such a case a year or two, it has been found that with a cessation of the disturbance of circulation the albuminuria and casts have entirely disappeared.

DR. C. F. FOLSON: The paper has been an exceedingly interesting one. For the last ten years I have examined the urine of all patients who have come under my care with a good deal of attention, and I have not been in the habit of considering a small amount of albumen as necessarily of very great importance in young people, especially between twenty and twenty-five, that is, provided I could find no other sign of disease; but in older people I think it usually has turned out that the disease has proved rather worse than the examination of the urine at first indicated.

I remember some fifteen years ago talking at quite a length with a physician in another part of the State who was very much disturbed at finding a considerable amount of albumen in his urine. He gave up his practice and went into the country, and thought he had a serious disease. He found he was pretty well after all, and went back to his practice. For quite a number of years a small amount of albumen appeared in his urine from time to time, and he finally satisfied himself that there was no serious trouble. I have the impression that Professor Wood examined the urine once, if not several times. Perhaps as typical a case

of this class as any is that of a young lady who came under my observation some five years ago. She belonged to rather a neurotic family. All the ladies of the family had most intense and violent vomiting during gestation. At the same time there was a good deal of physical strength, and the amount of work they could do was very much greater than that of ordinary people. This young lady had albumen in her urine between two and three years. I was never able to find casts of any kind. There was no secondary change in the heart, and there were no indications of any trouble beyond perhaps a certain amount of exhaustion as if from overwork. Professor Wood examined the urine in this case, and his result was the same as mine. At first there was about one-tenth per cent. of albumen, and in two or three years it disappeared. The urine was examined at various parts of the day and under various conditions, — as near menstruation as possible, and otherwise; and after that length of time the albumen disappeared. The urine has been examined frequently during the last few years, but the albumen has never reappeared.

I remember that one of the gentlemen who pays a great deal of attention to the examination of urine now, a graduate of a few years ago, said to me that quite a number of the house-officers examined their urine at the hospital one morning and all found it perfectly normal. Then all took a cold bath, after which they again examined their urine; and in a considerable number, if not in the majority, albumen was found.

There is another phase of the question that seems to be an exceedingly important one, and that is in reference to those cases of interstitial nephritis in which no indications are found in the urine after examination by careful people, and suddenly a hemiplegia perhaps, or some other serious symptom comes on, and the patient dies within two or three days, when advanced interstitial nephritis is found. I remember the case of a lady between fifty and fifty-five years of age, who was considered an unusually strong healthy woman for her age, and who spent a great deal of time in looking after her house-keeping because she wanted exercise. She happened to be at the house of a friend who had a sudden cerebral hæmorrhage which proved rapidly fatal; and almost instantly afterwards, curiously enough, she had hemiplegia. I saw her in the absence of her ordinary medical attendant. I made no examinations of the urine, for I was told that a careful examination had shown no trouble whatever. She died, however, within forty-eight hours; and at the autopsy one kidney was found to be about one-half the usual size, and the other about one-third the usual size. I dare say that careful and repeated examinations might have shown indications of disease; but the fact remains that the lady was apparently in perfect health until within a few days of her death, and that the urine, examined probably as carefully as by most physicians in their offices, showed no evidences of disease.

I have had three other similar cases, in neither one of which I happened to examine the urine myself. In all of them it was examined by the house-officers at the hospital whose duty it was to examine the urine, and who, I think, as a rule, do it more carefully than physicians who are in the habit of examining urine themselves do. I should be glad to hear what Dr. Wood would say about that class of cases. They certainly are very interesting.

DR. WOOD: The only thing I can state in that respect is that it has been my experience with students that the trouble is they do not allow the sediment to settle sufficiently. It is oftentimes necessary to let it settle over night before a suitable preparation of sediment can be obtained in order to detect casts. There is no doubt in many of these cases there is only a minute trace of albumen, and only a few casts in the sediment; and it requires a great deal of experience and skill to pick up the sediment in a pipette and put it on a slide so as to get a suitable specimen for examination.

DR. VICKERY: I believe I made the experiment to which Dr. Folsom referred; that is, I got the house-officers to make water when they got up in the morning, and then take a cold bath (it was in the winter), and then wait until some more urine could be excreted before they ate breakfast. There were seven house-officers at that time who did it, and a demonstrable amount of albumen could be got on using the acetic acid test and boiling, in, I think, all but two of the seven cases. I can succeed in the same thing in my own case, but I tried to see how universal that was, and two of my medical friends got no reaction whatever. I wonder whether they tried with the same care. The amount of albumen was very small. I think sometimes albumen is overlooked because the nitric-acid test is used, and the urine not allowed to sit long enough afterwards; for sometimes a clear trace will appear after a minute or two in the urine which at first seems perfectly guileless.

There is one kind of sediment about which I would like to ask Dr. Wood, namely, when the urine has stood all night and one goes to it the next morning and finds a very small amount of sediment — not sediment, but what ought to be sediment — floating in the middle of it in a round globe, looking very tantalizing, but very hard to get enough of to put under the microscope. I would like to know what Dr. Wood does in such cases.

DR. WOOD: The only direction I can give is to put the pipette into the middle of this, and take up as much as possible.

DR. G. W. GAY read a paper on

#### THE PROGRESS OF SOME LITIGATION CASES AFTER SETTLEMENT.

DR. A. H. NICHOLS: In confirmation of Dr. Gay's statement as to the very great frequency of these claims, I heard it stated recently by the attorney of a large corporation that the claims of last year against that corporation based upon personal injuries had numbered over 3,000; and it is well known that the different sessions of the Superior Court are now to a large extent given up to the trial of accident cases. This class of business, if it can be so called, is not only increasing but at a very rapid rate, and from causes not difficult to see. In the first place, employers of labor are now held, and properly I think, to a higher degree of responsibility in the case of accidents. This results in a measure from new legal enactments. In this State we have in this respect, followed the example set by the English Parliament, and embodied among our laws the Employer's Liability Act, which makes the employer of labor liable, under certain circumstances, for the accidents to workmen resulting from the carelessness of fellow laborers. Again, the decisions of the courts upon certain points of common law have been

reversed, as in accidents to very young children which can be illustrated by cases which have come under my own observation. For example, some twelve years ago a young child had its leg cut off by being run over by a horse-car. It was claimed by the defendant corporation that the parents, in letting their child run on the street unattended, were not in the exercise of reasonable care, and the judge, in ordering a verdict for the defendant, manifested considerable indignation that such a claim should be presented. But the Supreme Court within two years, in determining the amount of care which under various circumstances is to be required, discriminates between persons in different social positions; and in accordance with this new interpretation of the law, it is now left to the jury to determine whether or not the parents were in the exercise of care; and what would be deemed due care on the part of the wealthy would be very different from that which could be reasonably demanded of the very poor. So that here again the law creates an opening for various claims not heretofore presented, or if presented, speedily thrown out.

Another point to which my attention has been called is that of the novel and rather puzzling problems that have arisen in connection with these claims, and which are proposed to experts for solution. Surgeons are expected to give an accurate diagnosis where the results of an injury are complicated and obscure, and also to predict as to the future prospects of a claimant when no conclusive data are presented. They are called upon to enlighten the court as to the relationship or non-relationship of certain diseases and certain injuries, involving questions which have not been answered by the standard works. To advert, for instance, to a case tried some two years ago. A man was thrown by a collision from a carriage, without serious injury, and shortly after died of pneumonia. A suit was brought, with claim for a heavy *ad damnum*, based upon the theory that the pneumonia was the result of the accident. Now, as a matter of fact, at the time of the trial I was unable to find any authority for direct relationship between an injury such as was here sustained and any form of pneumonia; but recently Dr. Heilmann has reported in the *Berliner Klinischer Wochenschrift* a case of pneumonia apparently produced by a fall upon the side; and Blythe, even in cases of pneumonia of bacteriological origin, regards a fall, contusion of the chest, inhalation of irritating vapor, etc., as possible predisposing causes.

Now, to take another class of practical questions that come up. In making an award to compensate for the result of injury in a case of hernia, it was claimed that there was a possibility that death from strangulation might ensue, which contingency ought to be considered in estimating the award. This was before a board of arbitration; and while admitting the possibility of death from this cause, it was argued by the other side, that such a result was extremely improbable, and a small sum only was added to the award on account of that element. The man died within three months of strangulated hernia; and it was a matter of some consolation to learn that before death he admitted the lesion to be an old affair having no connection with the accident.

I was glad to hear Dr. Gay mention the importance of following up these cases after litigation is over; and it is certainly worth while to ascertain the subsequent progress and result, even at the expense of time and

trouble. I should like briefly to advert to one case occurring in my own practice, as showing how a mystery may be solved after a long period of years. In November, 1872, a man drove a milk-wagon, in the early morning, into an unguarded trench, but was not conscious at the time of injury to himself; and, having assisted in getting out his horse, walked home, a distance of two miles. In about two weeks he took to his bed, complaining of severe pains in back and hip, and there supervened impairment of sensation and complete loss of motion in one leg. At the trial, which occurred in Salem about a year after the accident, no diagnosis was attempted by any of the physicians who testified, the symptoms manifested being obscure and not of a localizing character; but as the patient was then improving, it was thought recovery would probably take place in one or two years. The plaintiff recovered \$10,000; but after the adjustment of the claim had repeated relapses, and ultimately removed to Colorado. The true nature of the trouble was not revealed until 1885, when, after an abscess formation, a concave fragment of bone was detached and discharged from the acetabulum, bearing the marks of an old fracture which must have been caused at the time of his fall; and the subsequent relief was complete and permanent. Time then, like a necropsy, may contribute to clear up the obscurity pertaining to the nature and extent of certain injuries such as are now made the basis of litigation.

DR. J. P. MAYNARD, of Dedham: I can corroborate very strongly the position taken by Dr. Gay, as being very fair and impartial. I am inclined to think that the surgeon or physician or expert summoned by a corporation goes to these cases with a little particle of prejudice. On the other hand, I think that the family physician stands in rather a more unbiased position. It is nothing to him whether his patient gets an award for damages or not. In some instances it has happened to me to come in contact with some one summoned by a corporation, who apparently did not want to know all the facts. They would not ask all the questions that were developed, and so perhaps could go back to the railroad and say, "I could not find any such great injury." More than that, it is perhaps a casual twenty-five-minute examination in order to catch the next train back. I think, as a rule, the attending physician who can watch the patient from day to day after the receipt of the injury, is in a better condition to judge fairly about the symptoms and the amount of the injury.

As to recovery after settlement, that is the main point we want to get at. I well remember the first bad railroad accident to which I was called, in 1850, I think. The case was tried, carried up two years, I think, after the accident, and the jury awarded what were considered high damages. The railroad carried it up on exceptions to the Supreme Court. Two years later it was again tried. The jury were unanimous in their verdict, which was for \$20,000, the first verdict having been for \$15,000. The case was tried a third time, and the jury awarded \$25,000. The railroad then decided not to contest the case further. That case I have had the opportunity of observing from the time of the accident until summer before last. After the first award there was certainly no improvement, nor after the second or third, excepting so far as the period of six years would improve her general health. Other cases of a similar nature have come under my

observation. It has not been my fortune to meet those cases which have recovered after settlement.

DR. E. G. WEST: I might allude to three cases I have had which have passed the litigation period. One of them is that of traumatic hysteria, so-called, which Dr. Knapp saw with me. About four months have now elapsed, and she is in the same condition as when the settlement took place. It was a very curious case in one respect; the hair on top of the head turned white overnight in a circumscribed spot about as big as a silver quarter of a dollar. This I am positive about, because it continued to grow out to the edge of the hair; and now, sixteen months after the injury, a few black hairs are beginning to show in the midst of the white ones. This patient had total hemianesthesia on the right side. She remained in bed about ten or twelve weeks, and eventually moved about the house. She is now practically in the same condition, and can simply go about with one of her daughters on each side. A year and a half ago I met with another case of traumatic neurosis or hysteria. The party received \$1,200. At the present time, although improved, still he has not recovered his health.

I have in mind another case, four years since the accident and sixteen months since the trial. The case is still in the Supreme Court; but the patient apparently does not think of the matter, and is practically in the same condition.

My experience is small, but as yet I have not met with any of those cases which got suddenly well immediately after damages were paid.

#### THE NEW YORK NEUROLOGICAL SOCIETY.

MEETING of April 7, 1891, DR. B. SACHS in the chair.

##### THE PATHOLOGY OF LANDRY'S PARALYSIS.

DR. HENRY HUN, of Albany, read a paper with this title. The case reported was that of an unmarried man, aged forty-five years, free from any syphilitic or rheumatic taint, who was suddenly attacked by paresis of the legs which, in the space of four days became a complete paralysis, following this the muscles of the trunk, arms, and parts supplied by the bulbar nerves became paretic in the order named, this paresis becoming more and more decided paralysis until death from bulbar paralysis put an end to the further extension of the process. The paralysis was a purely motor one, the sensory nerves not being involved, nor were the sphincters, although the paralysis of the abdominal muscles made the expulsion of the contents of the viscera difficult or impossible. As the result of a careful microscopical examination of the organs, the only lesions found were a slight cerebral and spinal meningitis of quite recent origin, and a degeneration of a few of the fibres of the anterior roots of the cauda equina.

After a careful consideration of those diseases of the nervous system most resembling Landry's paralysis, the conclusion was reached that no evidence had been brought forward which justified the abandoning of the term, acute ascending, or Landry's paralysis. It had not been shown that the numerous cases of the disease in which no lesion had been discovered, depended on faulty methods of examination, nor had any case been reported which was clinically a typical

case of Landry's paralysis, in which after death characteristic lesions were found, either in the central nervous organs or in the peripheral nerves. Acute ascending paralysis, defined so as to exclude all cases in which sensory symptoms were prominent or in which well-marked bulbar symptoms were not present, must, therefore, be regarded as a clinical entity for which no corresponding lesion had as yet been discovered. That there was some change in the nervous system causing the severe symptoms, could not be doubted, but this change was probably of a chemical rather than of an anatomical character. From the many points of resemblance which acute ascending paralysis bore both to myelitis of the anterior horns, and to multiple neuritis, this chemical change must affect either the motor cells of the spinal cord and medulla or the fibres springing from them; and although this chemical change was so great as to cause an entire arrest of the function of these cells or fibres, yet it left no trace in any altered character of cell or fibre, neither did morphia or strychnia leave any trace in the structure of the nervous system, of their fatal action. In regard to the nature of this supposed chemical poison, nothing was known. The general tendency of the present day was to consider it to be a ptomaine, and indeed the acute course, the fact that it often followed an infectious disease, and that it was associated with an enlargement of the spleen made it not improbable that Landry's paralysis was a germ disease. In further support of this view was the fact that Centanni and Eisenlohr had each found bacteria in the central nervous organs. In neither case were the bacteria cultivated. Centanni's case was so imperfectly observed during life that the diagnosis was doubtful. In a number of cases bacteria were looked for, but were not found, so that the hypothesis that Landry's paralysis was due to bacterial agency, was far from being proven, and the pathology of the disease still remained to be discovered.

DR. IRA VAN GIESON thought that Landry's paralysis was much more closely associated with cases of acute multiple neuritis, and acute poliomyelitis than was generally supposed. Landry, in 1859, had first accurately described several cases of ascending paralysis, although several observers had previously referred to the existence of such a disease. The speaker referred to several cases of acute multiple neuritis which had been reported, in which the motor symptoms had predominated, and in which the whole course of the disease had been in close accord with that of Landry's disease. He also reported several known cases of acute poliomyelitis which resembled very closely the disease in question. The clinical resemblance of these diseases was characteristic. It was well-known that multiple neuritis and poliomyelitis was usually caused by poisons of different kinds, such as the ptomaines resulting from the infectious diseases and from phthisis. Etiologically Landry's disease seemed to come under the same category as these two diseases.

Before a definite conclusion could be arrived at, as to the true pathology of Landry's paralysis, a more thorough examination of all nerve trunks with their branches and terminal filaments, would have to be made. Hitherto such observations had been unsatisfactory, because all the nerves could not be examined, for obvious reasons. For this consideration, the speaker thought that it should not be taken as conclusive, when it was stated that the peripheral nerves

were not diseased in Landry's paralysis, as thorough examination might have proven the condition the very opposite. As to the hyaline thromboses found in the central nervous organs, such changes occurred in ptomaine poisoning, but were not confined to cases of Landry's disease, as it might be present in any case of poisoning. Dr. Leonard Weber some six years ago had described a typical case of Landry's disease, in which the patient had entirely recovered in three months. In this case trauma, the shock of suddenly stopping a run-away horse, or the violent strain of pulling upon the lines had caused the disease, as the attack had come on subsequent to the accident. He did not think that the trauma militated against the poison theory. He was satisfied that if a more thorough examination of the nerves were made in these cases, our ideas of the pathology would become more definite.

DR. M. A. STARR thought that it was a question, whether the disease was of sufficient duration to cause neuritis and degeneration of the peripheral nerves, and whether such cases ever continued long enough for changes of this character to take place. It was certain that a myelitic process might cause a suspension of function without causing definite microscopical changes. He had never seen a typical case of Landry's paralysis, but had seen two cases which presented many of its symptoms. One was manifestly a case of diphtheritic paralysis, the other a case of beri-beri. He did not see how Dr. Hun could be satisfied that his case presented distinctive clinical symptoms. As for the case reported bearing a resemblance to multiple neuritis, it certainly differed from any case the speaker had ever seen.

#### CONTRIBUTIONS TO THE PATHOLOGY OF INFANTILE CEREBRAL PALSIES.

DR. B. SACHS read a paper on this subject. He stated that the mere form of the palsy, while pointing to a different location and a varying extent of the lesion, should not constitute a sufficient reason for the creation of special types, and that a hemiplegia, a diplegia, or a paraplegia might be due to the same morbid processes. Also that, although the majority of the cases were of the distinctly spastic type, flaccid paralyses did sometimes occur, which were unquestionably of cerebral origin; and again, that there were a few atrophic palsies due to lesions in the brain and not to lesions in the spinal cord or the peripheral nerves. These features, taken in conjunction with the occurrence of dementia or epilepsy and with the typical contractures and exaggerated reflexes, made the diagnosis a very positive one. Out of the two hundred cases seen, doubt, as to the spinal or cerebral origin was entertained in but a single instance. Hemorrhage, thrombosis, and embolism were positively proven to be the most frequent lesions in the acute cerebral cases. Other conditions so often cited were terminal and not initial morbid states.

Reasoning by analogy, Strümpell had concluded that a certain number of cases of acute infantile cerebral palsies were similar in every respect to cases of poliomyelitis anterior, except that the symptoms pointed distinctly to a cerebral and not a spinal trouble. It was natural, therefore, for him to claim that the gray matter of the cortex was subject to the same changes that affected the gray matter of the spinal cord; hence if we knew of a condition of poliomyelitis anterior

should there not be a condition of polio-encephalitis? There was no inherent reason why not, except that proof was wanting. Strümpell, himself, had abandoned the idea of a polio-encephalitis and now spoke of primary encephalitis, but even this theory must be accepted with some reserve. All the evidence which had been collected by the speaker was entirely against the assumption that a primary encephalitis was the rule in the acute brain palsies of children. Of the three autopsies which he had made, each represented a condition entirely different from the other two. The first case reported was not only interesting as a contribution to the pathology of this special subject but was able to stand on its own merits, as a case of tumor developing in the brain shortly before death. The history was as follows:

J. W., a healthy looking boy, eight years of age, was well until six and a half years old; then without any known cause was seized with convulsions, and developed right hemiplegia. When brought to the speaker, he had presented the symptoms of a typical spastic hemiplegia of the right side, including the face; and in this permanent involvement of the face presented, at least, one unusual feature. There was, furthermore, the history of loss of speech following the attack, and of repeated epileptic seizures involving the right hand only. His mental development was only a little retarded; his head showed the hydrocephalic condition, and during observation was noticed to increase in size. He had continued in good general condition for some time after coming under observation, when one day he suddenly fell down, and the right hemiparesis of old standing was found to have developed into complete paralysis. As far as could be learned, there was no loss of consciousness during this occurrence. The face was not more paralyzed than before; there was no incontinence of urine or faeces. Within a few days after this fall the boy developed fever, varying between  $101^{\circ}$  and  $103.5^{\circ}$  F. During this time a disturbance of vision was developed which ended in absolute blindness. Speech became more and more difficult; a mild stupor came on which gradually deepened into coma. Two weeks later intermittent opisthotonos was observed, which also became permanent. After five weeks, with the continuance of all the other symptoms, left ptosis and paralysis of left rectus externus and anaesthesia of the right cornea were added; the pupillary reflexes were lost, and the contractures of the right side increased. The ophthalmoscopic examination showed a retrogressive papillitis. Death finally took place eight weeks after the fall. The old hemiplegia was ascribed to a cystic formation probably due to hemorrhage over the left motor area. A tumor growing in the walls of the old cyst was the diagnosis made and adhered to by the speaker. In no other way could the increase of the former hemiplegia, without the addition of further symptoms, be explained. The tumor was supposed to be a glioma or gliosarcoma, but the development of basilar symptoms later on had led to the belief that a basilar meningitis had developed, and it was therefore erroneously assumed that the original tumor was of tubercular nature.

The autopsy was performed within twenty-four hours after death. The unusual size of the brain was at once made evident, from an accumulation of fluid within the ventricles to such an amount, that all trace of normal fissuration was entirely lost. While the brain was still *in situ*, a cyst occupying the left motor

area and the tumor in its walls could be distinctly observed. After the brain had been removed, further changes were seen at the base; first of all, a large cystic formation at the apex of the left temporo-sphenoidal lobe, pressing in upon and almost covering the left crus. The optic nerves were evidently atrophied, and the left abducens was extremely thin. Next in order came a large and hard tumor in the right temporo-sphenoidal lobe.

In spite of the manifold lesions found in the brain of this child, there was no difficulty in explaining the relations between these lesions and the symptoms during life, nor in determining the sequence in which these various pathological conditions became established. That the old hemiplegia was due to the cyst in the left hemisphere there could be no doubt. In view of the peculiar detritus which was found, and of the very sharply defined limits of the cyst, the speaker had no hesitancy in assuming the hæmorrhagic origin of this formation. The case enforced the point made in a previous publication of the author's, that the autopsies which were made soon after the beginning of the disease were those which would prove most reliable. In this case but three years had elapsed, and already the exact nature of the original process had become somewhat indistinct.

The histories and result of autopsies of two other cases were also reported. The knowledge of the pathological lesions underlying these various conditions was not only a matter of scientific curiosity, but it had a most distinct bearing point upon the treatment of these diseases. It was important for us to consider whether we had a right to interfere with the cerebral lesion in order that we might combat the development of idiocy or epilepsy, or whether it be possible — one or the other of these conditions having been established — to obtain relief by surgical procedures. The question could not be decided unless some such analysis of the morbid lesions was attempted, as had been given in a table presented to the Society. If we had to deal with a condition of porencephalus or with a condition of cortical agenesis, it was manifestly impossible to improve this state of things by an operation, and if such brains were incased within a microcephalic skull, even the recent operation of craniotomy would do no good. As for the birth palsies, no surgeon would be bold enough to attempt the removal of a subpial or subdural clot in a child only a few days old; and long before the child was strong enough to tolerate any such serious operation the mischief was done, an encephalitic or a sclerotic condition had been established for which the surgeon's knife could promise no relief. It was only in the cases of acquired cerebral palsies that one would naturally think of the possibility of operative procedure, and even in these great discrimination had to be exercised in the selection of cases.

DR. STARK had about made up his mind that the pathology of cerebral palsies was very uncertain, too uncertain to permit of surgical interference. He did not agree with Dr. Sachs in regard to operation in cases of cortical cysts. Of the nine cases on record all the patients had died. He thought that the idea of primary encephalitis as a cause in these cases, should be pushed into the background.

DR. L. C. Gray was then re-elected president, and Dr. J. A. Booth elected secretary of the Society for the ensuing year.

## AMERICAN MEDICAL ASSOCIATION.

THE FORTY-SECOND ANNUAL MEETING, HELD AT  
WASHINGTON, D. C., MAY 5-8, 1891.

## GENERAL SESSION. — FIRST DAY.

(Continued from No. 19, page 466.)

THE RELATIONS OF CONTRACT SURGEONS TO THE  
GENERAL PROFESSION.

A SPECIAL committee appointed last year by the Medical Society of West Virginia to consider this subject memorialized the Association, and appealed for its active co-operation to effect the redressing of alleged abuses. The memorialists asked consideration of the question, as to how far the rules adopted by railroad corporations for the government of the surgeons in their service intruded upon the rights of the profession at large, as set forth in the code of ethics of the American Medical Association. It was well known that large bodies of men were in the employ of these corporations, and that these men lived in widely scattered communities. The corporations had established systems of contract surgeons to attend employes and passengers injured by accidents. It was also well known that these corporations had adopted rules for the government of the surgeons and of those injured which demanded that these surgeons should assume entire charge of such employes or passengers, when injured, regardless of the rights of any outside medical men who might have been summoned, and be in attendance upon the injured prior to arrival of the company surgeon, even though the doctor first in attendance might be the family physician of the injured person. Notices had been in most cases served by the railroad companies waiving all responsibility in respect of injuries treated by non-contract men.

It was assumed by the memorialists that this condition of affairs placed the contracting surgeons in direct conflict with the spirit of the code of ethics, and was an infringement upon the rights of the physician first called. The practice of accepting passes as compensation, or in lieu of the regular fees customary to the profession, was detrimental to its interests by lowering the standard of the value of the surgical services, and was further demoralizing as it gave to these wealthy corporations services at far less rates than the profession charged to individuals. It seemed that if members of the profession were at liberty to make contracts to furnish an unlimited service of the kind referred to for passes, and in some cases for small fixed money payments, without affecting their ethical standing, all stigma of unethical or unprofessional conduct should be removed from those of the profession who contracted with private individuals to furnish medical or surgical services, including medicines, by the month or year, at fixed sums. A special committee was voted to sift the facts in respect to points alleged in the memorial.

## THE RUSH MONUMENT FUND.

This subject was again brought before the Association by DR. A. L. GIBBS, who for the seventh time reported slow progress towards the accumulation of the required appropriation. He made an earnest appeal for more enthusiasm in the matter, and propounded certain schemes to be adopted for the purpose of raising the necessary money; which were approved.

## THE ADDRESS ON GENERAL MEDICINE.

DR. L. L. SHURLEY, of Detroit, delivered this address.

He said he should present for consideration some points bearing on the relation of micro-organisms and toxins to the so-called zymotic or infectious diseases. Though laboratory work had done more than any other branch of science towards clearing up many vexed questions about physiological and pathological activities, yet to be of lasting value and guidance, it must agree with general and clinical observation; and there were instances where laboratory and clinical observations had crossed swords. He was aware that it was generally accepted that bacteria, or their spores, were the essential cause of most, if not of all, of the infective diseases and the results of bacteriological investigation during the last few years would seem to support such a doctrine for the following reasons: first, they could be isolated by color reactions, and thus directly connected with the diseased body when found; secondly, they required a certain time for development, corresponding to the period of incubation of such diseases. Many of them being ectogenic and saprogenic, anaerobic or aerobic, they could thus live until the opportunity for invasion offered. Being endowed with life, and multiplying enormously, they could resist destruction. Being protoplasmic and microscopic, they could more readily affiliate with animal fluids, cells and tissues. Existing in a passive or quiescent state as well as an active one, they could behave like vegetable seeds or spores and preserve a long period of latency.

For these and other reasons which might be adduced, we were led to believe that bacteria must be the cause in some way or other of the zymotic infectious diseases. But the question arose, How did they effect this result? Was it by mere local growth for a parasitic life by the secretion of a material from themselves? That is to say, Were they secreting cells, or did they induce at once chemical changes or fermentation of a destructive character, with the formation of new poisonous substances? It would be seen that many observers who were strong in their faith in the microbic origin of disease had not in every instance looked fairly at the question. The statement that no case of genuine cholera had as yet been reported in which the comma bacillus was absent had been disproved. In what bacteriological life was exemplified certain effects had been observed connected with development. The career of bacteria *ad interim* from one animal to another was not well known. In the case of many of them spores had never been demonstrated or their behavior formulated. Most of the species were destroyed by the healthy fluids or tissues, and hence their destiny depended upon a favorable nidus or pabulum, which meant disease. It was obvious that their artificial culture in media outside the body, or in the lower animals, could only approximately reflect their real natural growth and development; for in no instance was it possible to transfer the artificially cultivated micro-organisms to an animal with the absolute certainty that nothing else accompanied the bacteria. That certain species only appeared to be pathogenic implied a state of specialization analogous to living nucleated cells. That their action was local primarily in all cases might be assumed, because their behavior in no way showed that they themselves invaded or maintained their existence in the blood, or lymph fluids. Therefore it was probable that pathogenic bacteria developed only where previous disease or an abnormal state of the body suitable to them existed; that having found such they took root, as it were, and by their catalytic

action primarily, and secondarily by giving rise to a particular toxine, which in turn acted selectively as a tissue poison. If the bacilli of tuberculosis immediately produced the several diseases known as tubercular, why would any previously prepared nidus be necessary. If they, or their still undemonstrated spores, were constantly invading us, which was undoubtedly true, they must at once be destroyed, or by gaining access to the fluids of the body must set up mechanically or otherwise inflammation and peculiar effects as any other foreign body would. But as such micro-organisms must find just the proper conditions for development, or not develop, we might assume that such a result implied previous disease, such as caseation, whether tuberculous or not. Complex and delicate processes attended the changes of proteids, and by radical or atomic substitution one might be changed readily into the other. We could see how probable it was that these micro-organisms might operate by a peculiar property which enabled them to decompose or exercise a catalytic action on certain states and kinds of proteids.

It was manifest that diseases arising from the presence or entrance of micro-organisms must be therapeutically treated by attacking the cause or neutralizing its operation. The bacteria produced for themselves or from the organic substances which they attacked a poison which could be cultivated outside the body in some instances. Pathological chemistry had not demonstrated with exactness the nature of all these poisons or classified them, but it was fair to believe that this would be done in the near future. Although it was generally supposed that inorganic chemicals were not tissue poisons, but acted only upon the functions through the nervous system, still this view did not obtain when we observed the changes produced by iodine, bromine, phosphorus, arsenic, and the silver, gold, platinum and cupric salts, besides some of the vegetable alkaloids.

In consideration of the changes which many of the remedies underwent in the stomach and intestines by oxidation or other changes before absorption, it seemed to the speaker that the rational mode for the administration of drugs was to do so hypodermically, and in this way it was possible to command effects which could not otherwise be attained. Dr. Lauderer had obtained beneficial effects in phthisis from hypodermic injections of balsam of Peru. Behring had recently found that a number of chemical substances used hypodermically, such as aurochloride of sodium, naphthaline and trichloride of iodine were capable of neutralizing the poison of diphtheria in guinea-pigs, the latter substance being the most active of all. The same observer had also practised in diphtheria, and with good effect, the vaccination of animals with bacillus cultures. Better effects had been obtained from the administration of bromide of gold by injection, and from the bromide given in the ordinary way. The prompt results in the treatment of erysipelas by carbolic injections was well known. The superior effects of the treatment of syphilis by the hypodermic injection of cyanide and bichloride of mercury and chloride of gold and sodium were striking. Hypodermic injection of chlorodyne in profuse diarrhoea was superior to its administration by the mouth. Ergot administered even in considerable quantities by the mouth would often fail, whereas one or at most two, hypodermic injections of one-tenth or one-fifth of a grain of ergotin would generally stop a severe attack. Digitalis also

acted upon the cells and vascular system more certainly when so administered. He might also mention the beneficial effects of strychnia used in the same manner in typhoid conditions.

That animal poisons can be neutralized in the body he believed would soon be generally demonstrated. The recent experiments of Tyndall of New York for the cure of tuberculosis by vaccination promised well. Hemminger had stopped the diphtheritic process by the vaccination of the patient with an erysipelas toxine, and it was stated that people suffering from tinea tonsurans were immune from diphtheria. This would seem to show that there must be a sort of antagonism between animal and chemical poisons. Why could not more universal application be made of this principle with a view to obtaining more specific therapeutic agents. His object in choosing this subject had been to awaken a more general interest in physiological and pathological chemistry, and thus to hasten the period of release from empiricism.

#### THE ADDRESS ON SURGERY.

"Stricture of the Rectum: its Etiology, Pathology, Symptomology, Diagnosis and Treatment," was the subject of the address, by Dr. J. H. MATHEWS, of Louisville, Kentucky. He said he realized in discussing this subject that he should take positions contrary to the accepted teachings of the day, but assumed that the one great object of the meetings of the Association was to elucidate and discuss subjects that were in doubt, those mooted, not admitted.

In considering the classification of the varieties of stricture of the rectum, as given by Dr. Kelsey, he believed that for his purpose it was the best, as it embraced the varieties given and agreed to by the many different authors.

Congenital. Complete, Partial.

Acquired.

1. Spasm.
2. Pressure from without.
3. Non-Veneral. (a) Dysenteric; (b) Tubercular; (c) Inflammatory; (d) Traumatic.
4. Veneral. (a) Ulceration (either chancreloid, secondary or tertiary); (b) Due to unnatural vice; (c) Neoplastic (gunnata, ano-rectal syphiloma).
5. Cancer.

The first great division, it would be noticed, was congenital and acquired stricture. In writing of, or dealing with, stricture, the idea intended to be conveyed by the term was that of a pathological change in the tissues, a deviation from the natural brought about by disease; hence he objected to the consideration of congenital malformations of the rectum, or to define them under the head of strictures of the same, for the reason that it was misleading to do so. It would be more to the point to call them atresias of the gut. Exception could also be made to the term acquired stricture; and it was very easy to understand how one could acquire a stricture as a result of venery, but difficult to understand how one could acquire a spasmodic or cancerous stricture. He would adopt, for the sake of discussion, the classification into:

(1) *Spasm*.—To this form of stricture he should prefer two objections. First, if it was true that such condition ever existed, which he doubted, then it should not be classed as stricture at all, for the reason that no pathological change was manifested to constitute a stricture, and no treatment could be given it *per se*. In other words, it would be a symptom of some lesion or trouble outside the one called stricture. Secondly,

he believed that from the anatomical construction of the rectum it would be utterly impossible for its lumen to be so constricted as to be perceptible as an obstruction, by spasmodic contraction of its muscular fibres. In all his examinations of this part of the gut, he had never seen a spasmodic contraction that could be called a stricture.

(2) *Dysenteric*. — Although it was frequently stated that dysentery is a common cause of stricture of the rectum, he had never seen a case that convinced him of the truth of the statement, or that it was a cause at all. He had many times seen patients who gave him a history of having had dysentery, and who were treated for a long time for the affection, but close scrutiny of the case had revealed the fact that the so-called dysentery was caused by an already existing stricture and ulceration, dysentery being the result, not the cause of stricture. If a long continued irritation was kept up in the rectum, from any cause, the result would be, of course, an inflammatory exudate, resulting perhaps in ulceration and stricture; but in searching for this as a cause, the road to a conclusion had not been plain enough for him to put dysentery in the list as a cause at all for stricture of the rectum.

(3) *Tubercular*. — Since the discovery of the tubercle bacilli, and the demonstrations that convinced us of the effect on the tissues, etc., it was self-evident that tuberculosis was often met with in the mucous membrane and the structures of the rectum. If stricture and ulceration was the term used, he could make no objection to the classification of tuberculosis as a cause of ulceration. That ulceration frequently resulted from this diathesis or dyscrasia no one could doubt, but that the coincident stricture followed as from other well-known causes, notably syphilis, he could not agree. The disposition of tuberculous tissue everywhere was to break down. Before the capacious rectum was filled with tubercular deposit sufficient to stricture it, it would have broken down from ulceration, and so on, and it must be by deposition only that we could conceive of stricture from this cause; because cicatrization was so seldom, and so feeble, in these parts that it would be the rarest accident to find it. In no instance had he ever seen a stricture of the bronchi as the result of tuberculosis. There would be just as much reason to expect it here, or indeed more so, than in the rectum.

(4) *Inflammatory*. — This term was so broad and comprehensive that we must perforce of reason admit inflammation as a cause of stricture of the gut, indeed as the one grand and common cause; for if strictures existed from whatever cause, be it trauma, pressure, venery, dysentery, cancer, tubercle, syphilis, ulceration, or what not, it was inevitably due to the processes and products of inflammation, — in no other way could a stricture be formed. It might be argued that a lesion or wound, existing in the bowel, by the reparative process healed and left cicatricial tissue, and that the stricture was the result of the cicatrix, and not to plastic infiltration of the tissue. But there could have been no cicatrization if there had been no inflammatory process.

(5) *Traumatism*. — Under this head the author included ulceration following operations or wounds of the rectum, and cited the surgical operation done for hemorrhoids and fistula in ano. In all his practice, he had never seen such result follow either operation. He could understand how the cicatrix resulting from

the removal of too much skin from the anal region might cause a stricture of the anus.

If he were asked, what was the prime cause of stricture of the rectum, he would answer, *inflammation*. What caused the inflammation; in many cases he did not know, but ordinarily syphilis, cancer and trauma, if by trauma would be meant a wound or lesion from any or many causes. Outside of the two first named, cancer and syphilis, he was satisfied that no one could tell the cause that originated the stricture.

He wished to reiterate, that outside of these two well-recognized causes for stricture of the rectum, he was not prepared to admit any other as a well-known, recognized, indisputable cause.

The early symptoms of stricture in the rectum were very obscure and confusing. Indeed no stricture existed at all in the pathological changes going on in the gut, which conduced to this state. The great trouble was that the early symptoms were so masked or entirely *nil*, that no attention was paid to them by the patient, that when he was forced to consult a physician a very decided stricture might exist. The changes made manifest in the rectum were those of inflammation, and if from cancer, the condition of the blood-vessels, and the gradual deposit of the morbid material, together with infiltration of the tissue, went on so slowly and insidiously, that for a long time there were really no symptoms. When the stricture was within four inches of the sphincter muscle, it was easily diagnosed, whether malignant, benign or syphilitic, — the finger would detect it. It was a very different matter, however, to determine its character, and yet, to a certain extent, the treatment depended upon it.

He desired to say that, in his opinion, fully sixty per cent. of the strictures of the rectum were due to syphilis. Not venereal in the sense that many would have us believe, namely, by the infection of the rectum by chancrous pus, or by direct contact, but as a secondary deposit, the result of constitutional disease. As a means of diagnosis, the clinical history and observation of the case had much to do with forming a correct opinion. If it was ascertained that the patient has constitutional syphilis, I would consider that it was a strong point gained. I do not wish to be understood as saying that in every case where both syphilis and stricture exists, that the latter was caused by the former, but undoubtedly in the vast majority of cases this was true. Indeed, so firm was he in this belief, that if it was a question between cancer or no cancer, and it was decided that it was not malignant, ninety-nine out of every one hundred cases would prove to be syphilitic; for the reason that stricture, the result of benign ulceration, did not resemble in the least stricture from malignant deposition. To the contrary, syphilitic stricture did, to a degree, in its pathology, resemble malignant growths. To be plainer, malignant disease and syphilitic disease invaded the rectum as a deposit, infiltration of the sub-mucous tissues, etc. Ulceration here was secondary to the deposit caused by the friction of the passage of faeces, or the breaking down of the tissue, the result of the disease *per se*. Benign ulceration began with the damage done to the mucous membrane, and the plastic infiltration was secondary to it, the reverse of both the malignant and specific disease.

(To be continued.)

THE BOSTON  
Medical and Surgical Journal.

THURSDAY, MAY 14, 1891.

*A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.*

**SUBSCRIPTION TERMS:** \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,  
283 WASHINGTON STREET, BOSTON, MASS.

THE NINETEENTH ANNUAL REPORT OF THE  
LOCAL GOVERNMENT BOARD OF ENGLAND.  
SUPPLEMENT FOR 1889.

This report is one of the most valuable of the foreign sanitary documents, and contains the investigations conducted under the supervision of the medical officers of the Local Government Board.

A notable feature is the digest of vaccination returns in which it appears that the anti-vaccination movement in England has had some effect in inducing the people to violate the provisions of the vaccination laws, especially in certain districts. On the first of January, 1889, the percentage of children born in England in 1887, and still unvaccinated was 7.1 per cent. In London it was 9 per cent., and in the remainder of England and Wales it was 6.7 per cent. There was also an increase in the number of children returned as insusceptible to vaccination. There appears to have been great variability upon this point. For example, none of the children vaccinated in Shore-ditch, 3,994 in number, were found to be insusceptible, while in Fulham, one out of every 137 was so certified. As a just commentary upon these statements, it is also stated in the same report that Dr. Cory, who has performed over 38,000 primary vaccinations either with calf or humanized lymph, has in one case only, failed twice at an attempt at vaccination, and others had reported a similar experience.

The Report also contains the result of thirty-six local inquiries held by the medical inspectors of the Board, the majority of which related to the prevalence of infectious diseases in different localities. Fourteen of these had reference to diphtheria, a disease which appears to have increased considerably in its death-rate in the past three years. The deaths in London from this cause, according to the Reports of the Registrar-General, were 953 in 1887, 1,311 in 1888, and 1,588 in 1889. In about half of the sanitary districts of London, the disease had increased at least fifty per cent. in the three years; in many it had been doubled; and in some more than trebled. The Registrar-General adds that some part of the increase in diphtheria

may be due to a diminution under the heading of croup; but this can only be a partial explanation of the rise.

Dr. Klein continues in this Report his investigations upon diphtheria, which form a very important and valuable portion of the volume. His observations were greatly aided by the *field-observations* upon causation, which were afforded by the government inspectors.

He reports that, by the application of improved methods for the separation of the microbes occurring in superficial layers from those peculiar to the deeper portions of diphtheria membrane, he has succeeded in recognizing one particular bacillus which is constantly present in every membrane of diphtheria, and in identifying it from among others that are only occasionally present there. Of the occasionally observed bacilli, one in particular, which is relatively frequent in the superficial layers of diphtheria membrane, and which may also be found in healthy mucous membranes, has little morphological difference from the bacillus which is constant; and these two forms had, it would appear, been confounded together under a common name as "Klebs-Löffler" bacilli. But now Dr. Klein has recognized that these two forms, besides having minor morphological differences, differ significantly in their conditions of growth. The one grows, he tells us, at temperatures where the other refuses to grow; accordingly, they differ as to growth upon solid gelatine; and, notably, they also behave in very dissimilar ways, the one from the other, when milk is used as a nutrient medium. With these means of discriminating between the constant and the inconstant form of the Klebs-Löffler bacillus, and of thus isolating the former for experimental purposes, Dr. Klein appears to have demonstrated absolutely a specific bacillus which is necessarily present in diphtheria.

After first examination upon rodents without success, he resorted to cats, his selection of these animals having been determined by the considerations mentioned in the Report of the previous year (1888). Dr. Klein found that diphtheria membrane of human origin inoculated into the cat gave rise to morbid conditions remarkably similar to that which he had seen in cats sent to him from diphtheria households; conditions especially as witnessed in the kidney and in the cornea, which could be reproduced by subsequent inoculations of successive cats, and which possessed such diagnostic signs as he desired to have. From this point he proceeded to study the relation of bacterial forms found in diphtheria membranes to animal disease artificially induced.

He inoculated two milk cows with this bacillus with the result that one died in fifteen days, and the other, being killed on the twenty-fifth day, was found to contain several colonies of the same bacillus, free from other forms of bacteria. In the udders of each of these cows, small bacilli made their appearance which rapidly passed into pustules and crusted ulcers, in the lymph of which the *bacillus diphtheria* could

be demonstrated unmistakably, both in covered glass specimens and by culture. Two calves were inoculated with this lymph. They fell ill, and being killed on the twenty-fifth day, exhibited post-mortem appearances similar to those found in the cows.

Further observations were made as to the effect upon the milk of the inoculated cows. On the fifth day, from a healthy teat, carefully guarded against the introduction of accidental matter from the surface, milk was drawn into a sterilized beaker, and a drop (taken with proper precautions) was spread on the surface of nutrient gelatine. In three out of four tubes of this gelatine, bacterial colonies formed after the expected interval. There were eight colonies in all. All of these eight Dr. Klein reports, were "unmistakably colonies of the *bacillus diphtherie*." There were no other organisms present.

Finally, Dr. Klein records an outbreak of what he calls cat-diphtheria, beginning with two cats that had been fed upon milk from one or both of the inoculated cows.

A remarkable case of food-poisoning is reported to have come to the notice of the Board during the year. Diarrhea having been caused at Carlisle by the consumption of pork-pies, specimens of the pork, and also of certain gravy-stock, that had entered into the composition of the pies, were sent to Dr. Klein for examination. He fed mice upon these materials and produced disease in the intestines, and in the lungs of these animals. The lungs contained a particular form of bacillus, and this bacillus was out of a variety of other bacterial forms identified in the gravy-stock. The subcultures grown from the bacilli of the mouse's lung were found to have the same toxic property as the original gravy-stock.

The Report goes on to say: "The phenomena spoken of as 'food-poisoning,' productive, now of one, and now of another sort of definite malady among consumers of certain foods, are claiming, on ever-growing evidence, to be regarded as true infective diseases, as much so as scarlatina or tuberculosis. That they have not been generally admitted into this rank, arises, first, from the circumstance that some of them have seemed to be wanting in an incubative period; and secondly, because they are rarely recognized as transmissible from person to person. But, from our researches of this year, we derive some new considerations that materially affect the importance of 'incubation' as determining the infective nature of a poison."

Dr. Vincent Harris contributes a paper upon the "Relations of Bacteria with Digestive Processes," illustrated by observations upon the feeding of rodents with certain bacteria, those which were employed being the spores of anthrax, the bacillus prodigious, the bacillus tuberculosis, the bacilli of grouse disease, of typhoid fever, and of pneumonia.

A preliminary report is also given by Dr. Sidney Martin upon the "chemical changes which organic substances undergo, while supplying means of growth

to bacterial organisms," the organisms used for experiment being the anthrax bacilli.

Dr. Klein's researches upon diphtheria are very fully illustrated in the report by colored lithographic plates.

#### FURTHER EXPERIENCE WITH TUBERCULIN IN NEW YORK HOSPITALS.

At the meeting of the New York Academy of Medicine held May 7th, observations on the use of Koch's tuberculin in the treatment of pulmonary tuberculosis at a number of different hospitals were reported, and a general discussion on the subject took place.

Dr. F. P. Kinnicutt reported the observations at St. Luke's Hospital, Dr. A. L. Loomis those at Bellevue, and Dr. H. N. Heineman those at Mount Sinai Hospital. The experience thus far with the remedy seemed, in their opinion, to warrant the conclusion that while it should be employed with very great care, it was of decided benefit in many cases of phthisis in the early stages of the disease.

A report by Dr. E. L. Trudeau of the results of his experiments with tuberculin at the Adirondack Sanitarium at Saranac Lake, which was read by Dr. C. E. Quimby, showed that out of eight patients treated with it, one was cured, four were much improved, two were not affected, and one was rendered worse. Dr. Quimby also gave some observations on the use of tuberculin in connection with the pneumatic cabinet. In the course of the discussion which followed, Dr. A. Jacobi expressed the conviction that more had been accomplished by this than by any other remedy in the treatment of tuberculous diseases.

Whilst recognizing the perils of prophesying, we are inclined to the opinion that the ultimate verdict will be that tuberculin, or some allied remedy, is serviceable in the early stages of phthisis when carefully administered under favorable conditions.

#### MEDICAL NOTES.

UNIVERSITY OF PENNSYLVANIA.—At the graduating exercises held May 1st, one hundred and thirty-three candidates received the degree of M.D. The valedictory address was delivered by Dr. James Tyson, who spoke of the great loss which the University had just suffered by the death of Prof. Joseph Leidy.

THE LONG ISLAND COLLEGE HOSPITAL, Brooklyn, announces that the regular course of lectures will hereafter be six months in duration, and three courses of lectures will be required for graduation. Joshua M. Van Cott, Jr., M.D., has been appointed Professor of Histology and Pathological Anatomy, vice Frank Ferguson, M.D., who has resigned. The medical class of the present year numbered 250; the graduating class 82. There were 20,830 patients under treatment in the hospital and dispensary during the year 1890.

**MEDICAL EXAMINERS.**—Among the medical gatherings in Washington, last week, was one of the Medical Examiners of several States in which the practice of medicine is regulated by law. The meeting was for the purpose of organizing an association of different examining boards in order to harmonize the examinations of different States, so as to make the standard in different parts of the country as uniform as possible.

**ALABAMA HOME FOR AGED PHYSICIANS.**—Application for incorporation has been made in Alabama to found a home for superannuated physicians, the needy widows and orphans of physicians, and under some restrictions, for younger physicians unable to work. It is proposed to raise funds by subscription among physicians and others.

**A DISTINGUISHED CENTENARIAN.**—The English journals refer those who are sceptical of the real age of reported centenarians to Sir Provo William Parry Wallis, G. C. B., Senior Admiral of the British Fleet, who on April 12th celebrated his hundredth birthday. He fought on the British frigate *Shannon* when it encountered the American frigate *Chesapeake*, on June 1, 1813.

**SMALL-POX ISOLATION IN MEXICO.**—Two cases of small-pox were recently discovered in a Mexican town, and the authorities attempted to transfer them to the pest-house, but were prevented by an armed mob. The militia was called out and after a slight skirmish succeeded in preserving order.

**EPIDEMICS.**—Cholera is reported to be epidemic at Calcutta, where 341 deaths from this cause were registered during the last week in March. Yellow fever is prevalent at Rio Janeiro, together with a very pernicious form of malarial infection. The deaths from these two sources amounted to from 90 to 100 daily the latter part of the month of March. The plague has visited and still exists in Assir. Influenza seems to be increasing in Great Britain, and is reported from Mexico. The northern districts of China, which escaped in 1890, have suffered much during the past winter.

**ADMINISTRATION OF POWDERS.**—A correspondent of *La Médecine Moderne* recommends the use of cigarette papers for enveloping bitter and bad-tasting powders. If properly done the powder may be swallowed without tasting it at all. In the stomach the paper becomes macerated and the powder escapes.

**NEW MEDICAL LAW IN FRANCE.**—A new law regulating the practice of medicine has recently passed the French Chamber of Deputies. No one is allowed to practise medicine unless he possesses a diploma of Doctor of Medicine granted by the French Government after examinations passed before a State institution of superior medical education. This provision abolishes the lower grade of practitioners known as *Officiers de Santé*. Foreign medical men will be allowed to practise only after having obtained a diploma of Doctor of Medicine from the French Gov-

ernment. Exemption from some part of the examinations may under certain conditions be granted by the Minister of Public Instruction, but in no case shall such exemption apply to more than three of the prescribed tests. Foreign students wishing to obtain the diploma of Doctor of Medicine are to be subject to the same regulations as regards curriculum and examinations as French students; the diplomas and certificates of attendance which they have obtained in their own country may, however, be recognized by the proper authorities as equivalent to those required for "inscription" in a French medical school. The degree of Doctor of Surgery is abolished. It is enacted that every practitioner, under penalty of a fine varying from twenty to five hundred francs, shall, as soon as he has made his diagnosis, notify to the public authority any case of epidemic disease occurring in his practice, provided such notification does not involve a breach of professional confidence. Illegal practice, if accompanied by usurpation of a medical title, is punishable by a fine varying from one thousand to two thousand francs. Any one using the title of Doctor of Medicine without indicating its source shall be considered guilty of "usurpation of title," unless such title has been granted by the French Government.

#### BOSTON AND NEW ENGLAND.

**THE OUT-PATIENT BUILDING OF THE MASSACHUSETTS GENERAL HOSPITAL** has for some time been found too small. It has been decided to add a third story, and work has already been begun on the addition. It will not be necessary to close any of the clinics during the repairs.

**DISTRICT MEDICAL SOCIETIES.**—At the annual meeting of the Middlesex North Society, the following officers were chosen: President, C. M. Fisk, M.D.; Vice-President, F. C. Plunket, M.D.; Secretary, W. G. Eaton, M.D.; Treasurer, O. A. Willard, M.D. The Middlesex East Society elected as President, J. S. Clark, M.D.; Vice-President, C. C. Odlin, M.D.; Secretary, Daniel March, M.D.; Treasurer, J. O. Dow, M.D.

**COPPER SALTS IN CANNED VEGETABLES.**—The Massachusetts State Board of Health has called attention in its earlier reports to the practice of coloring certain canned vegetables, principally peas and beans, with metallic poisons, the chief article in use for such purpose being blue vitriol or the sulphate of copper. The practice is exclusively of French origin, and is prohibited in most civilized countries outside of France, English, Scotch, Belgium, German and other authorities have condemned the practice, and have excluded such articles from the markets by vigorous prosecutions. In this matter the State Board of Health adopts the principle which it has previously carried out in other similar matters, that the use of metallic poisons in connection with the food-supply is wrong, and should not be tolerated. The Board has, therefore, issued the following circular to persons dealing in such articles:

"You are hereby informed that a sample of marked \_\_\_\_\_, recently purchased at your place of business, was found on analysis not to conform to the requirement of the Statutes. You are respectfully warned that a repetition of its sale will render you liable to prosecution according to law. In the opinion of the Board, the sale of articles of food containing such well-known poisonous substances as the salts of copper is a violation of the Statutes relating to the inspection of food and drugs. The provision of the Statutes specially referred to are the following (chapter 263 of the Acts of 1882, section 3):

"An article shall be deemed to be adulterated within the meaning of this act, — in the case of food — (6) if it is colored, coated, polished or powdered, whereby damage is concealed, or if it is made to appear better or of greater value than it really is; (7) if it contains any added poisonous ingredient, or any ingredient which may render it injurious to the health of a person consuming it."

#### NEW YORK.

**ANOTHER CASE OF TYPHUS FEVER.** — A man who recently rode three or four miles from a downtown tenement-house to Mount Sinai Hospital in a street car was found on his arrival at the hospital to be suffering from typhus fever.

**SCARLET FEVER.** — Two large public schools, one with 2,000 and the other with 1,700 pupils, were temporarily closed last week on account of the occurrence of scarlet fever in the families of the janitors residing in the buildings.

**DA COSTA DEPARTMENT OF BIOLOGY.** — Dr. J. M. Da Costa, of Philadelphia, has made a handsome gift of books and microscopic specimens to the Da Costa Department of Biology of Columbia College, founded by his brother, and at the last meeting of the trustees of the college a formal vote of thanks was extended to him for his donation.

### Miscellaneous.

#### THE TREATMENT OF THE PYREXIA OF PHTHISIS.

WILLIAMS, in the *British Medical Journal*, March 28th, gives his experience with several different methods for reducing the pyrexia of phthisis, and sums up as follows:

"The pyrexia due to tubercularization is best dealt with by derivative measures, such as counter irritation, salines promoting secretion from other organs, and assisting expectoration. In the treatment of the pyrexia accompanying softening and excavation, measures which hasten these processes are found to be most successful, especially if combined with antiperiodics, such as quinine, salicin, salicylate of sodium to moderate the fever. The use of medicines solely directed to lowering the temperature of the body without promoting increase in the natural secretions is generally inadvisable. Our object in the treatment of phthisical pyrexia should be, not the reduction at all hazards of the temperature, but its lowering to the limits compatible with the comfort and well-being of the patients, and for this end much may be done, in addition to the discriminating use of medicines, by the simple means of frequent food combined with stimulants and rest in bed."

#### THE RED-ROSE PETALS AS A REMEDY FOR DIARRHŒA.

DR. ALEXEEVSKY, of Tambov,<sup>1</sup> emphatically draws attention of the profession to a simple, cheap, and safe method of treatment of diarrhœa, borrowed of the Russian popular medicine, and consisting in the internal administration of an infusion of the red-rose petals (*flores rose rubræ* or *domesticæ*). A large pinchful of the dried flowers should be taken to each tumblerful of hot water, and the vessel (carefully covered with a saucer or any other suitable object) left to stand in some warm place for about two hours. An adult should be given two or three tumblerful of the infusion a day, the daily dose for a child under five being a tumblerful or a cupful (given by portions in the course of the day). No sugar should be added, since otherwise "the taste of the remedy would be spoiled still further."

#### POWERS OF PERCEPTION OF CHILDREN.

BINET<sup>2</sup> has made a series of very interesting observations on the powers of perception of children. He experimented upon two little sisters, and found that the first color to be recognized was invariably red. When between one and two years old they could easily recognize the entire figure drawn on paper in outline of some common object, as a man, but it was several years before they could with certainty recognize an outline drawing of some individual part — as an ear or a finger. Binet also investigated how far the ideas of children are spontaneous, and how far they are recollections of dreams, but he found it difficult to come to any conclusion. He points out that at first children always regard themselves in the third person, and he gives several interesting conversations which show that their ideas about all objects are utilitarian; for example, they look upon a knife as a thing to cut with, bread as something to be eaten, and so on.

#### THE EFFECT OF GRAVITATION ON THE FORM OF THE THORAX.

REMEMBERING how constant and how potent is the action of gravitation, and arguing that the segments of the thorax were so many rings of more or less elastic material, Professor Anderson Stuart, of Sydney, in a communication made to the Royal Society<sup>3</sup> pointed out that if similar rings of any other elastic material were suspended in the same way the form of the thoracic segments should be reproduced, provided there intervened no other condition strong enough to counteract the action of gravitation. If hoops of erinoline steel, or even bands of paper were held between the finger and thumb, and gradually turned from lying in the vertical to lie in the horizontal plane, the forms of the thoracic segment of the quadruped, of the human fœtus, and of the human adult were successively reproduced. The complete reproduction of the features of the human adult thorax at its most characteristic level was most striking. The steel used was some six feet long and half an inch wide. As the hoop was made smaller the forms of the higher segments appeared in succes-

<sup>1</sup> London Medical Recorder, February 28th.

<sup>2</sup> Brit. Med. Jour. from Revue Pédagogique, Dec., 1890.

<sup>3</sup> British Medical Journal, March 7th.

sion. The points thus reproduced were so numerous that Professor Stuart urged they could not be mere coincidences, but that gravitation had a greater influence in determining the typical form of the thorax than would generally be admitted. This was supported by the shapes assumed by the steel rings when the mode of suspension was varied from the normal, as in deformities of the vertebrae; but the particular form in the individual — the thoracic deformity — was more or less accurately reproduced.

### STRYCHNINE IN SNAKE-BITE.

For some months much interest has been shown by medical men in Australia in the subject of the treatment of snake-bites by the subcutaneous injection of large doses of strychnine. According to Mueller, who brought the subject into notice, the drug should be freely administered until toxic symptoms are manifest. Although the practice has by some observers, both in and out of Australia, been condemned as useless, there appears lately to have been accumulated a large amount of evidence in its favor. Several cases are reported<sup>1</sup> in which poisoning by the "death-adder," an extremely fatal snake, has yielded promptly and sometimes wonderfully to the treatment. Large doses are tolerated and essential when the effects of the snake-poison are pronounced, the amount in some cases reaching more than a drachm of liquor strychninae (B. P.), or even more than a grain. Drowsiness, collapse, and even profound coma, are reported as relieved in a few minutes. When the patient is found profoundly under the influence of the snake-poison, a tenth to a fifth of a grain is given at once, and repeated if indicated or until toxic symptoms appear. The treatment has been used for the bites of several varieties of snakes.

### THE EFFECT OF ASPARAGUS ON THE URINE.

NENCKI<sup>2</sup> gives the results of his experiments to determine the cause of the familiar change in the odor of urine after eating asparagus. Four persons substituted asparagus for their midday meal; and the urine passed by them was collected, acidulated with oxalic acid and distilled. The volatile products were conducted into a solution of cyanide of mercury, causing a precipitate which was collected, washed, and treated with a small quantity of a five per cent. solution of hydrochloric acid. When again heated, the vapor, which had the characteristic odor of methyl-mercaptan, formed a bright yellow crystalline deposit in a solution of plumbic acetate. The odoriferous body in the urine is, therefore, in all probability, methyl-mercaptan. Previous experiments by Nencki and Sicker have shown that this substance is one of the products of fermentation of albumen, and also of gelatine, and that it forms one of the constituent gases of the large intestine. Indol and phenol are also derived from the putrefaction of albumen, and it is probable that other sulphur-holding bodies are similarly derived. As to its connection with asparagus, the author quotes an interesting communication from Dr. O. Loew, of Munich, to the effect that asparagin contains an organic sulphur compound, and that it is highly probable that

methyl-mercaptan is formed in the albuminous disintegration which takes place in the germination of the plant.

### PRESCRIPTIONS.

HERPES. — Besnier,<sup>1</sup> for herpes of the genitals, washes first with a weak carbohc acid solution, and then powders with the following:

R	Acidi tannici	.....	5 i.
	Bismuthi subnitrat	.....	gr. xij.
	Amyli pulv.	.....	3 iiss. M.

Leloir<sup>2</sup> uses this preparation:

R	Alcohol	.....	3 iij.
	Ext. cannabis indicæ	.....	3 iiss.
	Cocaine hydrochlor.	.....	gr. xv.
	Olei menth. pip.	.....	3 iiss. M.

Compresses moistened with this mixture are applied to the eruption.

### Correspondence.

[From our Special Correspondent.]

### AMERICAN MEDICAL ASSOCIATION.

WASHINGTON, May 9, 1891.

MR. EDITOR:—In view of the tropical heat which sometimes prevails in Washington during the latter part of May, it was decided last year at Nashville that the next annual meeting should be convened on the first Tuesday of that month; but fortunate the delegate who took with him his winter garments, for the weather, which for many weeks had been very mild, underwent on this morning a sudden change, a cold wave accompanied by a bleak wind and frost sweeping over this country; and inasmuch as no attempt was made to warm the places of meeting or most of the hotels, no inconsiderable discomfort was experienced by all, and especially by those who chanced to be clad in summer attire. Washington is doubtless the best planned and best paved city on this continent, and its public buildings and museums, designed on a scale seen only in the larger capitals of Europe, combine with numerous objects of historical interest in the immediate vicinity to render this metropolis the favorite place of meeting for conventions of every variety. The detail work of providing for the entertainment of such assemblies has been, therefore, reduced to a system, and the result is seen in the unusual accessibility of the halls used for the sections and general sessions, the latter being held in this instance in Arbuckle's Opera House.

The total attendance, as computed by Dr. Atkinson, Secretary, has not greatly exceeded one thousand, the majority hailing from Pennsylvania, Ohio, Indiana and Illinois, while the South and West were but meagrely represented. The attendance from New England was also small, not more than twenty coming from Massachusetts. A few women were scattered among the delegates, one of whom read a commendable paper. I heard it seriously stated that the attendance would have been much larger had the President been in town to receive the Association at the White House.

Rarely has the presiding officer been so well versed in the rules of parliamentary practice or so prompt in the despatch of business as Dr. W. T. Briggs, of Nashville, who displayed a keen scent for those eccentric and discursive individuals who, having contrived to get the floor on some question of privilege, talk on indefinitely to an impatient audience. "I arise to propose an amendment to the last motion," shouted an excited member. "You can't do it, sir; the motion not having been seconded is not before the house," was the firm, curt reply of the chairman. "I wish to speak on a point of order," exclaimed another in a stentorian voice, his hands filled with papers and docu-

<sup>2</sup> La Pratique Médicale, February 17th.

ments. "You may state your point of order, but nothing else," was the calm ruling made with asphyxiating effect. Thus in each and every instance, to the edification of the audience, these gentlemen endowed with more fluidity of diction than wisdom, were brought up short by this inhibitory process before they could get under weigh, while all who obtained a hearing were summarily suppressed whenever their remarks were not strictly confined to the subject under discussion. Perhaps the most frequent and best-known speaker was the venerable Dr. N. S. Davis, of Chicago, whose accurate familiarity with the constitution, by-laws and precedents of the Society, and whose forcible utterance commanded a respectful hearing, while his suggestions were, I believe, invariably adopted.

The motion passed at the last meeting, limiting all discussion to members seated on the floor of the house, had the good effect of sweeping off the platform the collection of ex-functionaries, who, having hitherto occupied this position of honor and thus obtained more ready recognition by the chairman, were accustomed to talk altogether too much. Rather than suffer in silence, these gentlemen are now reconciled to less conspicuous seats amongst their humbler colleagues.

Never has this Association occupied a stronger or more dignified position than to-day, and never has its usefulness to the profession and the general public been more clearly demonstrated. It should not be forgotten that while other societies may unite medical men in restricted localities, or those interested in special branches, this body with all its delinquencies constitutes the connecting link between physicians of repute from every part of the country; it has accomplished good work in the solidification of the profession, and in thus developing a powerful representative organization whose influence has been uniformly exerted in stimulating and fostering scientific work and promoting a higher standard of medical education in our schools and in advocating with the general government the adoption of measures in the interest of sanitary reform. For example, in the present session a resolution was passed appointing a committee to frame a memorial petitioning Congress to appoint a cabinet officer who shall be known as the Secretary of Public Health.

There was a noticeable improvement in attendance as well as in the tone and standard of papers read before the sections, a result clearly attributable to the painstaking efforts of their enthusiastic officers. The decision to employ in future stenographic reporters will render available to the profession much valuable information emanating from those best qualified to instruct, as in the intelligent discussion elicited by the papers read before the section of neurology on traumatic lesions of the cerebro-spinal axis. On the other hand, a serious difficulty arises from the excessive number of contributions presented, which inevitably tends to induce an unhealthy congestion in the proceedings, resulting in rapid reading of papers, while in the discussion the limitation to three or five minutes affords but inadequate time for the calm or accurate expression of one's opinions.

The history of the decline and fall of the Section of Dermatology was feelingly narrated by Dr. L. D. Bulkley, its chairman; while Dr. A. L. Guion, in behalf of the committee on the Rush Monument, gave a ludicrous description of the attempts made to collect subscriptions during the past year for this object, which apparently excites about as much interest in Philadelphia as has been shown in New York in the Grant Monument or in the proposed colossal statue of Adam.

In the Section in Obstetrics and Diseases of Women there were read, as I was informed, papers of a somewhat sensational order on the relation of female diseases to insanity, affirming that this connection is not duly appreciated by asylum superintendents, and consequently gynæcologicalists are, as a rule, debarred from practice in institutions for the insane, whereby curable local disorders constituting the primary cause of mental derangement are at times left totally uncared for. This arrangement was not, however, reinforced by the citation of any convincing

or conclusive facts, and the impression left by the few isolated instances quoted was that the alleged evil was purely problematical and theoretical.

The reception tendered on Tuesday evening by the resident physicians of Washington, in the spacious intercommunicating parlors and ball-room of the "Arlington," proved in all respects a brilliant success. Delegates were made mutually acquainted by the indefatigable exertions of the local reception committee organized by Dr. Lincoln, and the affair was enlivened by the presence of many ladies in evening costume and by the music of the Marine Band.

It was predicted that the reception given by Dr. Hammond at "Belcourt" would be an elegant affair, as it undoubtedly proved, according to the reports of the local newspapers; but your correspondent visited instead the Corcoran Art Gallery, which was thrown open to physicians and their families on the same evening, and where the attendance was said to have been not less than a thousand. The report of the nominating committee on Thursday, recommending Hot Springs, Arkansas, as the next place of meeting, led to the only acrimonious debate, which terminated in the substitution of Detroit by a vote of 143 to 105.

In this connection it may not be out of place to call attention to a very general desire which has been expressed for several years, and especially by Southern men, that an invitation might be extended to the Association to visit Boston, where it has not met since the last year of the war, when a visit to the Confederates imprisoned at Fort Warren was one of the excursions offered. Now that Massachusetts has again been brought into prominence by the election of Dr. H. O. Marey to the highest office within the gift of the Society, may we not hope that its wishes in this respect may in the near future be gratified?

On Thursday, a party of about 250 made an excursion to Mount Vernon; and in the evening many delegates with friends visited the Army and Navy Medical Museum, where they were received by Surgeon-General Charles Sutherland, Dr. J. S. Billings and others; while other delegates inspected the curiosities and wonders of the National Museum as displayed by electric light. On the same evening the private art gallery of Mr. Thomas E. Waggaman was courteously thrown open.

The seemingly chimerical project of convening a Pan-American Medical Congress at the Columbian Exhibition at Chicago, encountered no opposition, and a committee headed by Dr. Charles A. L. Reed, of Cincinnati, was appointed and organized to put the plan into execution.

A. H. N.

## PAINLESS LAPAROTOMY WITHOUT ANÆSTHESIA BY INHALATION.

PODUNK, May, 1891.

MR. EDITOR:—We knew that you city doctors had come to look upon laparotomy as quite a trivial affair, but it is a surprise to us to learn that one of your number does the operation so deftly that he is able to dispense altogether with anæsthesia by inhalation, and only uses an anodyne, when in, I suppose, some very complicated case he is obliged to inflict pain.

That drug which he uses must be a remarkable one. In the tantalizingly brief report of a case that has been sent me (on pink paper in a pink envelope), he says: "Case of pain in the abdominal section, of a deep-seated nature, where I used EXODYNE, it relieved the pain, and patient slept well that night."

We want to hear more about his cases, and we are going to invite him out to the next meeting of our district society to tell us about this wonderful "Antipyretic, Anodyne, Hypnotic, Sedative, etc." which some philanthropic souls banded together under the name of the Orange Chemical Co. so generously offer, at one dollar the ounce, to meet a long-felt want for a new combination of coal-tar derivatives. Yours truly, OCCIDENTAL.

METEOROLOGICAL RECORD.

From whooping-cough Chicago 4, New York 3, Brooklyn and Nashville 2 each, Boston, Cambridge and Gloucester 1 each. From erysipelas New York and Chicago 3 each, Boston 2, Washington 1. From malarial fever New York 4, Brooklyn 2.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MAY 2, 1891, TO MAY 8, 1891.

By direction of the Acting Secretary of War, paragraph 5, Special Orders No. 24, JANUARY 29, 1891, from this office, granting Major JULIUS H. PATOZKI, surgeon, six months' leave of absence, is so amended as to grant said leave on surgeon's certificate of disability. S. O. 99, Par. 15, A. G. O., May 1, 1891.

First Lieutenant JOSEPH T. CLARKE, assistant surgeon, is relieved from duty at Fort Riley, Kan., and will report in person to the commanding officer, Camp Poplar River, Mont., for duty at that station, relieving First Lieutenant JEFFERSON D. POINDESTER, assistant surgeon. First Lieutenant Poindester, on being relieved by Lieutenant Clarke, will report in person to the commanding officer, Fort Niobrara, Neb., for duty at that post. S. O. 102, Par. 14, A. G. O., May 5, 1891.

Captain WALTER D. McCaw, assistant surgeon, is relieved from duty at Fort McPherson, Ga., and will report in person to the commanding officer, Camp Pilot Butte, Wyoming, for duty at that post, relieving Captain GRACE E. BUSHNELL, assistant surgeon. Captain Bushnell, on being relieved by Captain McCaw, will report in person to the commanding officer, Fort McKimby, Wyoming, for duty at that post. S. O. 102, Par. 14, A. G. O., May 5, 1891.

Captain WILLIAM P. KENDALL, assistant surgeon, relieved from duty at Fort D. A. Russell, Wyoming, and will report in person to the commanding officer, Fort Douglass, Utah Territory, for duty at that post. S. O. 102, Par. 14, A. G. O., May 5, 1891.

Captain GUY L. EDIE, assistant surgeon, is relieved from duty at Fort Douglas, Utah Territory, and will report in person to the commanding officer, Fort Niobrara, Neb., for duty at that post, relieving Major TIMOTHY E. WILCOX, surgeon. Major Wilcox, on being relieved by Captain Edie, will report in person to the commanding officer, Fort Huachuca, Arizona Territory, for duty at that post. S. O. 102, Par. 14, A. G. O., May 5, 1891.

Major JOSEPH B. GIRARD, surgeon, is relieved from duty at Alcatraz Island, Cal., and will report in person to the commanding officer, Benicia Barracks, Cal., for duty at that post, relieving Major JOHN H. JANEWAY, surgeon. Major Janeway, on being relieved by Major Girard, will report to Philadelphia, Pa., and assume the duties of attending surgeon and of examiner of recruits in that city, and, in addition to his duties in Philadelphia, will perform the duties of post surgeon, Frankfort Arsenal, Pa. S. O. 102, Par. 14, A. G. O., May 5, 1891.

First Lieutenant JULIAN M. CABELL, assistant surgeon, is relieved from duty at Fort Niobrara, Neb., and will report in person to the commanding officer, Fort Buford, North Dakota, for duty at that post, relieving Major VALERY HAYARD, surgeon. Major Hayard, on being relieved by Lieutenant Cabell, will report in person to the commanding officer, Fort D. A. Russell, Wyoming, for duty at that post. S. O. 102, Par. 14, A. G. O., May 5, 1891.

Captain LOTIS A. LA GARDE, assistant surgeon, is relieved from duty at Fort Assiniboine, Mont., and will report in person to the commanding officer, Fort McHenry, Md., for duty at that post, relieving Major CHARLES L. LYRNE, surgeon. Major Lyne, on being relieved by Captain La Garde, will report in person to the commanding officer, Fort Assiniboine, Mont., for duty at that post. S. O. 102, Par. 14, A. G. O., May 5, 1891.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE, FOR THE TWO WEEKS ENDING MAY 2, 1891.

AUSTIN, H. W., surgeon. Detailed as member of Board of Examiners, Marine-Hospital Service. April 21, 1891. Detailed as chairman of Board for physical examination of officers and candidates, Revenue-Marine Service. April 29, 1891.

GODFREY, JOHN, surgeon. Detail as member of Board of Examiners revoked. April 21, 1891.

IRVING, FAIRBANK, surgeon. Detailed as recorder of Board for physical examination of officers and candidates, Revenue-Marine Service. April 29, 1891.

CARRINGTON, F. M., passed assistant surgeon. To proceed to Fernandina and Jacksonville, Fla., as inspector. May 1, 1891.

STIMPSON, W. G., assistant surgeon. When relieved, to proceed to Savannah, Ga., for temporary duty. May 2, 1891.

OMITTED FROM PREVIOUS LIST.

BROWN, B. W., assistant surgeon. Detailed as medical officer, Revenue Steamer "Rush," during summer cruise. April 14, 1891.

# OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MAY 9, 1891.

G. P. BRADLEY, surgeon, detached from "Mohican," and placed on waiting orders.

T. C. WALTON, medical inspector, GEO. A. BRIGHT, surgeon, and J. M. STEELE, passed assistant surgeon, ordered to Naval Academy to examine applicants physically for admission.

S. H. DICKSON, surgeon, ordered to the "Constellation."

PHILIP LEACH, passed assistant surgeon, detached from Naval Academy, and to the "Constellation."

W. H. RUSH, passed assistant surgeon, detached from "Saratoga," and await duty to sea.

L. W. ATLEE, passed assistant surgeon, detached from Navy Yard, League Island, and to the "Saratoga."

C. D. W. BROWNELL, assistant surgeon, ordered to Navy Yard, League Island.

## ANNUAL MEETING AND CENTENNIAL ANNIVERSARY OF THE NEW HAMPSHIRE MEDICAL SOCIETY.

The executive committee of the New Hampshire Medical Society issues the following preliminary circular:

"CONCORD, N. H., May 5, 1891.

"At the last meeting of the Society," it was voted that the executive committee, in connection with the officers of the Society, arrange the programme for the centennial anniversary in 1891. Your committee have held several consultations with the officers and the committee of arrangements, and it has been decided to hold a three days' session. Monday, June 16th, at 11 o'clock A. M., to be a general session, when papers and discussions will occupy the time until evening. Monday evening will be set apart for the Meeting of the Council, and an opportunity for the members and their wives to attend a reception tendered the Society by Mrs. Dr. Russell.

"Tuesday will be devoted entirely to the centennial exercises, consisting of a special excursion and collation in the forenoon, papers relating to the centennial history of medicine in New Hampshire in the afternoon, and the anniversary dinner in the evening. (The expenses of the excursion and the anniversary dinner will be paid by the Society.) Wednesday, the Society will hold a morning session, to hear any papers left over from Monday, elect officers, and attend to all other routine business."

## SOCIETY NOTICES.

MASSACHUSETTS MEDICAL SOCIETY, SUFFOLK DISTRICT. — The Section for Clinical Medicine, Pathology and Hygiene will meet at 19 Boylston Place, on Wednesday evening, May 20th, at 7.45 o'clock.

Papers. — Dr. J. Payson Clark, "Sarcoma of the Nose, with Report of a Case"; Dr. Cheever will open the discussion. Dr. C. F. Folson, "Some Points regarding General Paralysis"; Dr. Fitz will open the discussion.

Dr. C. Irving Fisher, Superintendent of the Tewksbury Almshouse, will make a report on "Hospital Accommodations for Syphilitic Patients."

ALBERT N. BLODGETT, M.D., Sec'y., 300 Boylston St. E. G. CUTLER, M.D., Chairman.

THE FIFTH STATE SANITARY CONVENTION OF PENNSYLVANIA will be held at Altoona, Pa., on Friday and Saturday, May 15th and 16th, under the auspices of the State Board of Health. C. E. DUDLEY, M.D., Altoona, Pa.

## OBITUARY. JOHN J. MILLIAU, M.D.

Dr. John J. Milliau, late surgeon and Brevet Brigadier-General, U. S. A., died in New York on May 8th. He was born December 28, 1828. He graduated from the College of Physicians and Surgeons, New York, in 1850, and the following year was appointed assistant surgeon in the United States Army. During the next few years he served on a number of important expeditions in the West, and when the Civil War broke out, in 1861 he was appointed medical inspector of the Army of the Potomac. He afterwards became medical director of the Third Army Corps, and was present at the siege and capture of Yorktown, the battles of Williamsburg and Seven Days, the Seven Days' Fight, and the second battle of Bull Run. In 1862 he was medical director of the hospitals at Frederick, Md., and in 1863 and 1864 was medical director of the Fifth Army Corps; being on duty at Gettysburg, Spotsylvania, Petersburg, and many other important battles. In the latter part of 1864 he was compelled by ill health to withdraw from active work in the field, and was ordered to New York. Between 1867 and 1869 he served as medical director of the Third Military District, Department of the South. December 2, 1869, he was brevetted lieutenant colonel for gallant and meritorious services before

Richmond. March 13, 1865, he was brevetted colonel for gallant services during the war. September 28, 1869, he was brevetted brigadier-general for merit and distinguished services at Hart's Island, N. Y., during the cholera epidemic, where he alone remained to attend to the sick. In 1876 he resigned from the service, and since then has continued to reside in New York, where he was greatly esteemed by all who came in contact with him. General Milliau has, during the past few years, held many positions of honor and trust, and for eight years was one of the Commissioners of the State Board of Charities.

## DEATHS.

ABRAHAM COLES, M.D., of Newark, N. J., died at Monterey, Cal., May 2d, aged seventy-eight.

W. H. BOLLING, M.D., Dean of the University of Louisville, Ky., died, May 5th, aged fifty-one.

EDWARD MAYNARD, M.D., D.D.S., dental surgeon and inventor, died in Washington, D. C., May 3d, aged seventy-eight. In addition to the advances in dentistry with which his name is connected, he invented a large number of appliances connected with fire-arms, among them the Maynard rifle, well-known throughout the world.

WILLIAM W. DOW, M.D., M.M.S.S., of Somerville, Mass., died, May 8th, aged fifty-seven. He went through the Harvard Medical School, supporting himself in the meantime by keeping a small drug store. He graduated in 1869, and immediately began practice in Somerville, where he had since remained. In 1873 he was appointed city physician, and served for several years.

DR. EDUARD GOLTDAMMER, of Berlin, Chief of the Bethany Hospital, and the author of several medical works, died, April 11th, aged forty-nine.

## APPENDICITIS: A YEAR'S EXPERIENCE IN PRIVATE PRACTICE.

BY J. W. ELLIOT, M.D., BOSTON.

BETWEEN March 15, 1890, and March 15, 1891, I saw thirteen cases of appendicitis in private practice, being called in consultation as a surgeon to take the responsibility of operating or not. Of these cases, six were operated and seven were not operated. Four of the operated, and all of the non-operated recovered; making a total of thirteen cases, with eleven recoveries and two deaths.

Of course, these figures cannot be used to show the comparative mortality of operated and non-operated cases, as in this instance all the worst cases were operated, while the less severe ones were left to recover, and I should consider it a grave error in judgment if any case were allowed to die unoperated on, if seen in time.

These results are more favorable than I have had in any previous year. This I attribute partly to increased experience, but principally to the fact that I have seen these cases much earlier than formerly. Seven of the cases were seen within the first three days of the attack, whereas, in former years I have usually been called on the seventh or eighth day. If practitioners always called their consultations on the second or third day, the mortality would be much lower than it is at present.

## PERFORATED GANGRENOUS APPENDIX, TOGETHER WITH PART OF THE OMENTUM REMOVED ON THE THIRD DAY: RECOVERY.

CASE II. Miss Mary G., aged fifty, was seen in consultation with Dr. Prior of Malden, late at night, April 7, 1890. A month earlier she had had a chill. She was taken three days before with sudden acute pain in the right lower abdomen. Chills and vomiting soon followed. Morphia was given. When I saw her she had a listless, drowsy, sick expression. The abdomen was generally swollen and tympanitic. There was tenderness and slight induration on the right side. The bowels were constipated. Temperature  $101.2^{\circ}$ , pulse 92. The next morning there was no change in symptoms; abdomen very tense; bad expression. At a consultation with Drs. Sullivan and Prior an immediate operation was decided on.

The operation was difficult on account of a poor light in a small room, and a very fat patient.

The incision was two inches inside the anterior superior spine of the ilium, in the linea semilunaris. When the peritoneal cavity was opened, the omentum presented. It was inflamed, thickened, and adherent in every direction; and it was very difficult to get beyond it. It was finally pushed aside, and the finger went into a mesh of adhesions which felt like a cobweb, and seemed to extend in every direction; the cæcum was reached, but the appendix could not be found in this mass of adhesions. There was no indication in which direction to search. Finally in desperation I tore the whole omentum free, and pulled it out through the wound. On its thickened and inflamed edge I noticed a deep gangrenous groove about large enough to hold a finger. From a former experience where I had found the appendix wrapped in the omentum, I immediately realized that this was the mark

of the sloughing appendix; enlarging the wound and searching in the direction whence this part of the omentum came, I found the appendix very low in the iliac fossa, much thickened, so that when free it stood erect on the cæcum, resembling a man's thumb in size and shape. It was so gangrenous that it filled the room with a vile stench. I ligated it at its base, and cut it away. I also cut away a large part of the inflamed omentum which had been lying against the appendix, because it had evidently become infected with the gangrenous process. There was not a drop of pus to be found. After disinfecting the appendix stump, the region which had been occupied by the appendix was filled with iodoform gauze and drainage-tube and the wound left open.

The appendix and its mesentery were thickened to about the size of a large thumb, and about two inches long. The appendix was gangrenous and perforated. The omentum removed was about the size of a hand, very dense and inflamed, and showed a deep hollow where it had wrapped itself about the appendix. This hollow was intensely inflamed, and on its surface the gangrenous process was beginning.

The temperature fell to normal on the next day. The iodoform gauze was removed on April 10th, when the tympanites had entirely disappeared. The bowels moved spontaneously on the fifth day. The wound healed beautifully without complications. Her convalescence was retarded and protracted first by a localized pneumonia on the left side on April 21st, the temperature rising to  $102^{\circ}$ , and by a crural thrombosis also on the left side, which made its appearance on April 27th, just as the lung trouble was beginning to mend. These processes were undoubtedly septic, having their origin in the already infected omentum, as the wound always looked healthy. She sat up on May 15th.

In July a small point in the wound opened, and in November the ligature was removed by Dr. Prior. Recovery was complete.

## RECOVERY AFTER TWO MONTHS, WITHOUT OPERATION.

CASE III. Mrs. N., fifty-four years old, was seen April 27th, for Dr. H. W. Cushing (in his absence from town), on the third day of the attack.

The attack began with sudden, severe pain in the right side, with vomiting and constipation, and a sharp rise in the temperature ( $102^{\circ}$ ). During the first two days there was a gradual abatement of the symptoms, the temperature falling to  $100^{\circ}$ . On the third and fourth day all the symptoms were worse. There was more pain and tenderness, and the temperature rose to  $102^{\circ}$ . The abdomen was somewhat distended, and there was great sensitiveness to pressure in the right side. Operation was advised and refused. On the following day there was a great improvement in all the symptoms, which lasted for several days.

When seen again on May 10th, the pulse was 110, and the temperature  $101.8^{\circ}$ . The abdomen was swollen and tympanitic. The right iliac region was filled with a hard mass which was tender and painful. It extended nearly across the lower part of the abdomen and down into the pelvis, pushing the uterus over to the left side. Drs. Fitz and Homans saw her, and advised against operation. With the rest in bed, all the symptoms slowly and gradually subsided, and the patient recovered after an illness of over two months.

I feel perfectly sure that in this case there was a perforation of the appendix with pus formation, which was absorbed; and I think she ran great risk in not allowing the operation to be done.

**PERFORATION OF THE APPENDIX AND GENERAL PURULENT PERITONITIS; EXCISION OF THE APPENDIX AND DRAINAGE; RECOVERY.**

**CASE VIII.** The patient was first seen on December 30th, in consultation with Dr. Sullivan, of Malden. He was a healthy man, thirty-five years old. He had had a bad colic two months before I saw him, which he thought was due to eating peanuts; this had kept him from work for one day.

On the evening of the December 26th, he was taken with a colic while at supper, which grew worse at night. On the afternoon of the next day the pain became very severe, and he sent for the doctor. Dr. Sullivan found him with a temperature of 102.5° F., and in so much pain that he was not relieved by a half-grain of morphia. He could feel a tender lump in the right side, which he took for the inflamed appendix.

On December 28th, the bowels were moved with oil. On the 29th, there began to be a general distention of the abdomen, which gradually became more distended and tympanitic. The temperature and pulse fell to normal. On the 30th, the morning temperature was 99° F.; the evening temperature was 100° F.; the pulse was 84. He had a great deal of pain, requiring five-eighths of a grain morphia and half a grain opium. The pain which had previously been in the right iliac fossa had become more severe on the left side than on the right.

I first saw him on the evening of the 30th. The abdomen was very much distended and tympanitic. There was a sense of resistance, tenderness and dullness on the right side. There was a distinctly fluctuating point just inside the anterior superior spine of the ilium. The general condition was surprisingly good. Dr. Sullivan and I agreed that an operation was necessary, and as it was then late in the evening, we arranged to do it the next morning.

December 31st, the fifth day of the disease, the patient had had a fairly good night, had passed a considerable quantity of gas, but was still very tender on the right side. The pulse was 84, temperature 98° F. The abdomen was very tense, and his general appearance was not quite so good as the night before.

At the operation under ether, a hard lump could be felt in the right iliac region. An incision two inches long was made directly over this lump. As soon as the peritoneum was opened, a half-pint of bad smelling pus ran out. The lump proved to be the omentum rolled up on the appendix, and much inflamed. The pus cavity ran directly across the pelvis in various directions to the left iliac fossa; there seemed to be several collections of pus between the intestines, which were opened with the finger. Suspecting that it had gravitated into the pelvis, the finger was pushed into Douglas's fossa, and a quantity of pus evacuated. In short, there was general purulent peritonitis. Another opening was then made in the median line, and a long glass drainage-tube put down into the pelvis. The whole abdominal cavity was then thoroughly irrigated through both openings with hot water. The inflamed omentum could be seen through the incision in the right side, and was pulled out through the wound; on unrolling it, there was a gangrenous groove on its sur-

face, which corresponded in shape and size to the appendix. Searching in the direction indicated by this gangrenous groove, the appendix was felt and pulled out. It was ligated and removed, also a piece of inflamed omentum as large as a man's hand. The wounds were left open, and filled with three drainage-tubes and iodoform gauze.

The appendix with its mesentery, which was much inflamed, was as large as a man's thumb, and at least five inches long. The whole appendix was much inflamed, and half an inch from the tip was a large gangrenous perforation, an eroded opening large enough to admit the finger-tip. Only about three inches of the appendix was removed, owing to the difficulty of freeing it from its adhesions.

The patient recovered without complications after two months' illness.

**RECOVERY WITHOUT OPERATION.**

**CASE IX.** Mrs. L., aged twenty-three, was seen on the first day of the attack. She had sudden severe pain in the right side with tenderness on pressure. Temperature 103°, pulse 120. There was obstinate constipation. The pulse and temperature remained the same for three days, and then gradually fell to normal; rose again on the eighth day, and then gradually returned to normal. There was no very severe pain, and the patient always looked bright and cheerful. The tenderness in the right side lasted for three weeks. She recovered after six weeks' illness. No operation was advised, but the continued high pulse and temperature gave considerable anxiety.

**REMOVAL OF A PERFORATED APPENDIX ON THE FOURTH DAY; GENERAL PURULENT PERITONITIS; DEATH ON THE FOURTEENTH DAY.**

**CASE XI.** The patient, a mulatto student aged twenty-five, was seen on February 8th, in consultation with Dr. S. E. Wyman of Cambridge, on the fourth day of the attack. He had been perfectly well, but constipated for a few days. On February 4th, he had three movements of the bowels with pain and vomiting after a late supper.

February 5th, he got up and dressed, but soon had very severe pain with a chill and vomiting. Dr. Wyman found him at twelve o'clock cold, pale and shaky (the appendix was probably perforated at that time). He gave morphia one-third of a grain. The pulse was 84, temperature 101.4°. The abdomen was tender and dull on the right side.

February 6th, the abdomen was slightly tympanitic. Temperature 100°, pulse 95.

February 7th, there was less pain and tenderness, still tympanites. Pulse 90, temperature 99.8°. Great pain and vomiting after a movement of the bowels.

February 8th, the abdomen was more swollen and tympanitic. The respiration was entirely costal. Pulse 116, temperature 98.2°. I first saw him in the evening, and found a very much distended abdomen, with dullness and a slight sense of fluctuation in the right side. The pulse was high and irregular; the tongue dry; and he had a very bad expression.

I operated at once in a small student's bedroom, by the light of a kerosene lamp. Pus spurted out as soon as the peritoneum was incised. A large pus cavity was evacuated, and washed out with warm water. The appendix was immediately recognized in the cavity by a finger in the wound. It was separated, pulled

out and excised. It seemed probable that there was more pus in the pelvis and general peritoneal cavity, but further exploration was abandoned on account of the poor general condition of the patient. The wound was packed with a drainage-tube and iodoform gauze, and left open.

The appendix was as large as a little finger. There was a sharp outlined perforation half an inch from the tip, resembling in size and shape a pistol-ball wound. The tip of the appendix was gangrenous. There was a gangrenous, false membrane lining the abscess cavity, and also covering part of the appendix. There were faeces in the abscess cavity. The general peritoneal cavity was opened.

February 9th, the operation was followed by a severe shock. There was great pain, vomiting, hiccoughing and a chill. Pulse 130, temperature 99.8°.

February 10th, the bowels moved after a high enema. Hiccoughs.

February 11th. Pulse 80, temperature 98.6°. Three movements of the bowels; less distension; less pain. The patient seemed to be getting well.

February 13th, hiccoughing and vomiting very troublesome. Patient not so well. Pulse 120, temperature 100°. The abdomen seemed more swollen over the pelvis.

February 14th. Ether was given, and the abdominal cavity explored with a finger through the wound. Several collections of pus were found between the intestines and in the pelvis. The peritoneal cavity was washed out with hot water; three drainage-tubes and iodoform gauze were stuffed into the cavities. In short, there was general purulent peritonitis, which progressed in spite of all we could do, and the patient died ten days after the operation.

In this case the operation was done too late. If it had been done on the second day it might have saved the patient's life.

SLoughing APPENDIX CAUSING PERFORATION OF THE CÆCUM AND BEGINNING PURULENT PERITONITIS; REMOVAL OF THE APPENDIX AND CLOSURE OF PERFORATION ON THE FOURTH DAY; DIED ON THE FOURTEENTH DAY.

CASE XIII. The patient, a man of thirty years, was seen on February 28, 1891, with Dr. Breck.

February 26th, he had pain in the navel, and vomited, but worked all day.

February 27th, there was more pain. The patient went to bed, and took a cathartic, which caused the bowels to move several times with great pain.

February 28th, the patient had a chill. Pain was quieted by one-quarter of a grain of morphia. Pulse 110, temperature 100°. Hiccoughing. When I saw him first the abdomen was only slightly distended, but very rigid. There was pain and slight tenderness in the umbilical region. There was a wave on percussion over a limited area just inside the anterior superior spine of the ilium. He had a bad expression. Operation was advised.

February 29th. Pulse 90, temperature 99°. The patient slept comfortably with morphia, but looked very hollow-eyed and sick.

At the operation pus ran out as soon as the peritoneum was opened. Several pus cavities were broken open between the intestines. The appendix was found to have sloughed out of the cæcum, hanging only by its mesentery, and leaving an opening in the cæcum

large enough to admit a finger. The cæcum was much inflamed, gangrenous in part, and thick and friable as heavy orange peel. The perforation left by the sloughing appendix was with difficulty sewed up. The abscess cavities were washed out and drained with tubes and iodoform gauze. The wound was left open.

The patient had no indication of farther pus formation, but the bowels remained distended, and could not be moved. The wound was explored under ether several times, and no trouble could be discovered.

March 6th, the patient was constantly hiccoughing and vomiting. Pulse and temperature were about normal. Bowels obstructed. Under ether the cæcum was pulled out through the wound, and all the intestines in the region examined for obstructing bands; finally, a small band was found pulling on the cæcum, and cut. The wound in the cæcum sewed at the first operation was found to have united, and was tight. The next day the bowels were moved with a glycerine enema, but they could not be thoroughly emptied, and the strength gradually failed, and the patient died.

My idea of the case is that the cæcum was paralyzed by the gangrenous inflammation, as often happens in hernia, and that that caused the inactivity of the bowels.

The cases of McBurney, Worcester of Waltham, Stimson and others published within the last year, make a distinct advance in the treatment of appendicitis. They have demonstrated the fact that the mortality of cases operated on in the first three days is not high, that in the very early operations the appendix can often be excised before it ruptures, or pus forms outside. In such cases, the operation can be completed as a real antiseptic laparotomy. In contrast with such clean, early operations, the later operations must deal with patients already more or less septic, with burrowing pus cavities, and gangrenous sloughs. The later operations will, of course, have a much higher mortality.

No one has yet been able to lay down rules which will help us to decide at the outset which cases are going to be severe, and which mild. Dr. McBurney thinks there is no better way of improving our methods of diagnosis than by exploratory incision. Dr. Worcester believes we should operate in every case as soon as we can make the diagnosis.

Although such rules may be the best policy to be adopted from our present knowledge, or want of knowledge, it is only a phase, and cannot be the last word on the subject. For it is not scientific to operate on every case when we know beforehand that more than one-third (Fitz thirty-six per cent.) recover, and do not require an operation. It is also unsatisfactory to say that after a certain experience in these cases one acquires a good judgment as to which cases will require operation. This is nevertheless true, and it is on this line that the question must be patiently worked out by observing severities and combinations of symptoms, rather than by operating before symptoms appear. Even a series of fifty successful early operations would not contribute to the question of "When is the operation necessary?"

From my point of view there are in general two classes of cases in which an experienced observer finds himself on solid ground: the very severe ones, and the very mild ones. There is no doubt about the extreme cases of both classes. The very severe cases should be operated on at once, within the first three

days. The sicker the patient the earlier the operation; and the mild cases should be left and carefully watched.

Every one is alarmed at the more obvious symptoms of high pulse and temperature with great pain and vomiting, and in these days such severe cases are more often getting their proper consideration, and are operated on early. I have only one word of caution to add in regard to these cases, and that is, not to postpone the operation on account of some slight improvement. I have seen dreadful results follow such postponements.

The apparently mild cases require the greatest experience and good judgment; cases with pulse and temperature under  $100^{\circ}$  are the ones I have most often been called to operate on when it was too late. In such cases the appearance of a "tender tumor" (not fecal) in the right side, or of a distended, tympanitic abdomen indicates a local process which is dangerous, and requires an operation. A rigid, retracted abdomen, with pain, is also a local symptom of great importance, which is often overlooked. Continued vomiting, hiccuping, rapid respiration, delirium, stupor, cyanosis, anxious face and chills, are symptoms which occurring even in apparently mild cases indicate a grave condition which requires immediate operation. Any one of these symptoms occurring in a doubtful case should settle the doubt in favor of operation, and occurring in a more severe case with high pulse and temperature, the operation is urgent.

With experience, one learns more and more the exact value of the different severities and combinations of these symptoms. As seen above, high temperature and pulse were not always the earliest indications of danger in these cases; but a rise in pulse is much more important than a rise in temperature, in fact, a high temperature for a day or two is not uncommon in cases which recover rapidly. In five of the above cases which recovered without operation, the temperature rose to  $102^{\circ}$  or higher, and in three to  $103^{\circ}$ . The average highest temperature in the cases operated on was  $100.8^{\circ}$ , and in the cases not operated on it was  $101.5^{\circ}$ . From which it appears that the temperature has risen higher on an average in the less severe cases.

I have come to regard the local symptoms (pain, tenderness, tumor, rigid abdomen, distension, tympanites), as the most reliable early symptoms. As soon as these symptoms are present to any considerable degree we are in the presence of real danger. When a tumor is noted on the second or third day, and is obscured later by distension and tympanites, the probability is, that an inflammation which started local is becoming general. Continued vomiting and hiccuping usually occur later, and indicate that peritonitis has begun. Anxious face, chills and cold extremities may appear on the first day, and if so, usually indicate that a perforation has taken place. Stupor, delirium, rapid respiration and cyanosis come at the very end, when it is usually too late to operate.

The various combinations of these symptoms are more difficult to interpret. Well-marked local symptoms should give great weight to even slight constitutional symptom. In other words, if one can make out by physical signs that a serious inflammatory process has started in the region of the appendix, it is a great advantage to operate before the constitutional disturbance has become severe. As an illustration:

Case XI was seen on the fourth day with only slight constitutional symptoms. Pulse 108, temperature  $100^{\circ}$ . Yet immediate operation was advised and done, because there was severe pain, and a greatly distended and tympanitic abdomen. General purulent peritonitis was found at the operation.

On the other hand if the local symptoms are somewhat obscure, one should give less weight to the constitutional symptoms. To illustrate: Case V was of a young lady who had pulse 120, temperature  $103^{\circ}$  for three days. No operation was advised, because the abdomen was not swollen; there was no tumor, and while the tenderness in the side was considerable, the pain was only moderate, and she had a bright, cheerful expression. Between these extreme examples of severe local symptoms, with slight constitutional symptoms, and *vice versa*, there is the possibility of infinite variations, which must be observed and correctly judged in each case.

To add to the complexity of this subject, both local and constitutional symptoms may be moderate in a grave case. To illustrate: Case XIII was seen on the third day. Pulse 90, temperature  $99^{\circ}$ . There was no tumor, slight tenderness, but great pain in the umbilical region. The abdomen was only slightly tympanitic, not distended, but very rigid. The operation was decided on, on account of the rigid abdomen, and a hollow-eyed, sick expression of the patient. Hiccuping was also a symptom in this case. At the operation we found a quantity of pus, and the appendix sloughing out of the cæcum. In such cases the general expression of a person who is very sick, an expression almost impossible to describe, but known with great certainty to skilled practitioners, may be the most important symptom in the case. In this connection let me say that nothing tends so much to make the patient look bright, and to deceive the doctor and the friends, about the patient's real condition, as opium. Opium should be withheld as much as possible until the real gravity of the case is understood, and the question of operation is settled.

From this year's experience I feel confident that a great advance can be made with experience and a careful study of the above symptoms. For these reasons, I have rejected the dictum to operate as soon as you can make a diagnosis, but would operate on the first appearance of any unfavorable symptoms. In other words, I think one is tolerably secure in waiting when all the symptoms are mild, if he understands the value of the various symptoms, and is quick to act on the first unfavorable one.

There is one pathological point which I will speak of, because I have never seen it mentioned by any one else. In two of the above cases, and in two more operated on last year, I have found the gangrenous and perforated appendix completely rolled up in the omentum. In the early stages of such cases one finds, clinically, simply a hard mass in the right side. In Case II no pus had formed on the third day when the operation was done. In Case VIII, operated on the fourth day, the appendix had not been so securely covered, and the general peritoneal cavity had been infected. From the operative point of view it is important to know that when the omentum is seen brawny, inflamed and rolled up, that it contains the gangrenous appendix, and should be excised with it. Also when a gangrenous groove is seen on the surface of the omentum it is a guide to the position of the appendix.

A CASE OF ABSCESS AND SOFTENING OF THE BRAIN WITH CHRONIC DISEASE OF THE TYMPANUM.<sup>1</sup>

BY J. ORNE GREEN, M.D.

ELIZA P., aged thirty, received a blow behind the right ear six or seven years ago, followed within a week by discharge from the ear. Since then has had occasional pain in the ear with renewed discharge lasting for a week or two and then ceasing for some months. For five years on rising suddenly and on going down stairs has been dizzy, followed occasionally by vomiting.

About one year ago, after the birth of her last child, she was sent to the Danvers Insane Asylum, where she remained eight months, and came out one month ago against advice. By a letter from Dr. C. W. Page, the superintendent, I get the following history:

"E. P. was admitted July 5, 1889. Previous history states mother was insane for thirty-two years. Cause of this attack 'overwork and worry over scandal.' Youngest child three months old. Has had hysterical attacks; always cranky. Mental change noticed July 1, 1889; neglected her baby, and was confused and maniacal. On admission heart, lungs and abdominal organs normal; pupils equal and respond to light; tongue not well protruded, straight and coated; knee-jerk increased. No symptoms pointing to local disease of brain or mastoid were observed. Restless, depressed, incoherent and deluded. Became more quiet in a few days and seemed more depressed; quite stupid.

"July 12th, quite violent. July 22d, hallucinations of hearing. August 1st, noisy at night, and threatening and noisy in the day-time. August 8th, reported by the night-nurse to have had a fit; was stiff, breathed heavily, and was apparently unconscious for some time. Up to about the time she went home, she continued restless, mischievous, silly, and at times violent. She showed considerable facial tremor when talking, but speech was only slightly affected. Had a peculiar manner of squinting when looking intently at anything, the left eyelid closing more than the right. She was discharged March 9th. The diagnosis made soon after admission was acute melancholia or possibly general paralysis."

One week after her return the right ear began to pain her again and to discharge. The pain was referred to the whole frontal region and to the right mastoid. She was treated at the Massachusetts Charitable Eye and Ear Infirmary for purulent inflammation of the tympanum and mastoid, but when unable to attend there was seen by Dr. E. M. Plummer who, in addition to the above symptoms found a temperature of 101° F. April 5th, she was better after leeching of the mastoid; but on the 6th was suffering more than ever. On the 7th she was again easier, but on the 8th there was stupor and stertorous breathing all day, and on the 9th she was wildly delirious, requiring restraint. On the 10th she was better and voluntarily entered the City Hospital.

I found her conscious, calm, perfectly rational with a temperature of 100° F. and a pulse of 80. Examination of the right ear showed a large central perforation of the drum-membrane, the tympanic mucous membrane pale, slightly oedematous and with a slight

mucous discharge; there was no oedema or swelling of the walls of the meatus or of the remnants of the drum-membrane. The mastoid was somewhat tender over its lower half with slight oedema there, but not more than could be referred to the leech-bites. Watch  $\frac{3}{4}$ ". There was slight diffuse swelling in front of the tragus in the centre of which an enlarged gland could be felt. April 13th the swelling of the tragus and of the mastoid had entirely disappeared, the otorrhœa had ceased, the tympanic mucous membrane was pale and normal. Temperature 98.6°; pulse 64. The pain, however, continued constant, was referred to the entire right side of the head, but was worst over the temporo-sphenoidal lobe. Pressure over the mastoid, temporal and malar bones developed equal sensitiveness, the mastoid not more tender than the other bones. There were no other symptoms than the pain. She was perfectly rational and quiet.

April 15th she began, for the first time, to show symptoms of pressure on the brain, the pulse falling to 45 and becoming very weak. She was drowsy and stupid, but when roused complained of severe pain in the head; was seen by Drs. Gay and Knapp, but an operation was deemed inadvisable. In about two hours she became totally unconscious with a dilated and immovable pupil in the left eye followed in another half-hour by the same condition in the right eye, but during the day she became semiconscious again. April 16th she had a sudden and very severe exacerbation of pain on the right side of head followed by coma; pulse 45 with occasional remissions. The pulse and temperature then began to rise, the former to 102, the latter to 180°, and she died cyanotic during the day.

The autopsy by Drs. Prescott and Greenwood gave the following results: The dura mater showed nothing abnormal; the pia dry, but otherwise negative; convolutions flattened. On attempting to remove the brain an abscess about the size of an English walnut was ruptured; it was situated in the right temporo-sphenoidal lobe, its outer wall of brain-substance being only one-eighth of an inch thick. The fluid contained in the cavity was sero-purulent, not offensive, with numerous white flocculent masses. To the inside of the abscess, towards the centre of the brain was an area of softened brain-substance partly involving the optic thalamus, of about the same size as the abscess. The ventricles and rest of the brain-substance showed nothing abnormal. The lateral and petrosal sinuses were normal.

The heart was small, the cavity of the left ventricle quite small owing to hypertrophy of its walls. The mitral orifice admitted one finger-tip and the tricuspid four finger-tips. The curtains of the mitral valves were somewhat thickened. The other organs were negative except for congestion.

The petrous and mastoid bones were removed and examined by myself. The dura-mater over the petrous bone was normal and not adherent; on stripping it off the bone itself showed no signs of inflammation and swelling. The mucous membrane of the tympanic cavity was free from inflammation and swelling. The drum-membrane showed a large central perforation, but was free from inflammation; its anterior portion was calcified. On sawing open the mastoid it was found to be solid bone throughout, but absolutely without signs of inflammation; the only traces of the antrum were two or three pneu-

<sup>1</sup> Read before the Boston Society for Medical Observation, February 2, 1891.

matic cells about the size of a pin's head situated in the extreme anterior part close to the tympanic cavity.

The pathological diagnosis was cerebral abscess and softening, mitral stenosis and the results of otitis media suppurativa in the right ear.

#### REMARKS.

I at first thought a mastoid operation was indicated, but failing to find distinct indications of mastoid disease in oedema of the meatus or external tissues and the sensitiveness of the bone not being confined to the mastoid, I kept the case under observation and found a steady improvement in the ear symptoms. In fact, the inflammation of the tympanum, which undoubtedly existed two weeks before, rapidly subsided, and no inflammation of the mastoid remained. The specimen shows merely the results of some previous inflammation in a permanent perforation of the drum-membrane and osteo-sclerosis. No mastoid operation could have accomplished anything.

The brain-abscess was a most favorable one for operation. At the time the diagnosis can be said to have been established by the symptoms of pressure it was decided, at the consultation, that the general condition precluded it; and the softening, in addition to the abscess, would seem to show that this decision was a wise one at that time. Whether an operation could have been successful earlier would depend upon whether the abscess was the primary lesion and the softening secondary or the reverse. The exact sequence of events is uncertain, and I should be glad to have opinions on the point whether the abscess occurred first and the softening was secondary and the beginning of a second abscess, or whether the abscess was a recent breaking down of a spot of chronic softening. The combination of a blow, chronic ear-disease, insanity and valvular disease of the heart was a singular and confusing one.

The results of the autopsy do not explain the cause of the abscess directly. I think we can say that the recent ear-disease was certainly not the cause, for there was not the slightest retention of pus and not a trace of recent otitis of any form nor involvement of the labyrinth. Whether the abscess could have been the result of some previous otitis, which in all probability caused the osteo-sclerosis, may be also a question, but the contents of the abscess, sero-purulent, not offensive, not inspissated and not encapsuled is wholly against the abscess being a chronic one. The valvular disease of the heart was not the cause for there were no vegetations to have caused thrombosis.

The only localizing symptom for an operation in this case was the localized pain which was referred exactly to the spot of the abscess, and the operation would have been a simple one. Localized pain, however, in otitic brain-abscess at least, is not to be relied upon for indicating the seat of the abscess. In the *Boston Medical and Surgical Journal* of May 31, 1888, I reported in full a case of otitic abscess of the cerebellum in which the pain was referred in the most direct way, and always to the parietal and temporal regions where the autopsy showed there was no trace of disease.

These two cases afford some interesting contrasts. In the present case there were many symptoms apparently calling for an opening of the mastoid, and only from watching the case could I finally decide that it

was uncalled for. The autopsy showed that I was right in that regard, but it also showed that I had followed the simple guide of localized pain I could readily have opened the brain-abscess. The previous case gave no indications for opening the mastoid, and localized pain indicated the temporal region as the seat of the abscess, while the autopsy showed that the mastoid was the chief seat of the ear-disease, and if I had done the ordinary mastoid operation I should have reached the caries of the bone and could, and probably should, have immediately emptied the cerebellar abscess which communicated with the mastoid cavities by a large carious opening; while the localized pain would have carried me into the temporo-sphenoidal lobe where there was not a sign of disease.

This symptom of localized pain is so often spoken of as indicating the seat of the abscess that I beg to call attention to some recent statistics of Körner's.<sup>2</sup> He has analyzed one hundred cases of otitic brain-abscesses, and in speaking of pain says it is of little value for localization. Of twenty-one cases of cerebellar abscess in eight only was the pain referred to the occiput, while in three the pain was referred to the forehead; and in five cerebral abscesses the pain was referred entirely to the occiput.

#### OBSERVATIONS ON ANTEFLEXION OF THE UTERUS.<sup>1</sup>

BY JOHN B. SWIFT, M.D.

It has been my fortune to meet with a number of cases of this affection, and I present for your consideration to-night my observations of them. They have presented a rather constant group of symptoms, and the description of one case will answer for all.

The patient presents herself complaining of dysmenorrhœa. She is generally of spare figure, and what is called a nervous disposition. We learn that the catamenial function was established at the regular time, was normal as to amount and duration, but has always been painful; the pain beginning before the flow appeared, of a cramp-like nature, and relieved when the flow became established. As time went on the pain became more severe, lasted longer, and between the periods there has been a constant leucorrhœal discharge of a thick consistency like the white of an egg.

The general health has suffered, dyspeptic symptoms with constipation are present, the appetite is poor, often capricious, and morning nausea quite frequent. There is pain in the back, and often also in the groins, especially on the left side. This pain is increased on standing or unusual exertion, and locomotion is often difficult. Frequently there are urinary disturbances, the patient being obliged to empty the bladder often. If she is married she is sterile.

This describes the so-called congenital cases, though my belief is that they are not truly congenital, but are due to non-development of the uterus caused by mal-nutrition at the time of puberty.

In the acquired cases, the uterus has developed well and the catamenial function has been normally established and performed for a more or less longer time, but through mal-nutrition or disease, the uterine tissues

<sup>1</sup> Read before the Boston Society for Medical Observation, February 2, 1891.

<sup>2</sup> *Archiv. für Gynäkologie*, vol. xlix, p. 14.

have become softened, and the flexion takes place either suddenly on some unusual exertion or gradually by pressure.

On bi-manual examination, four conditions are found; (1) The cervix points in the normal axis but the body is bent forward; anteflexion of the body.

(2) The body is in the normal axis with the cervix pointing in the axis of the vagina; anteflexion of the neck.

(3) The cervix is in the axis of the vagina, and the body is bent forward almost parallel with it; anteflexion of body and neck.

(4) Body and neck are both bent forward, but the whole organ is displaced backwards; retroversion of an anteflexed uterus.

The flexion generally takes place at the junction of body and neck, and causes a diminution of the calibre of the canal, which may be demonstrated by the passage of the sound, thus presenting an obstacle to the free discharge of the menstrual blood, and so causing the dysmenorrhœa, as the obstruction must be overcome before the blood can get out. In other words, each menstrual period is like a labor; the blood collects in the cavity of the uterus and is forced by the obstruction, the pain subsiding when the flow becomes established, because the canal has been dilated.

Menstruation being the natural way of relieving the pelvic congestion which is present at this time, and this being interfered with causes many of the other symptoms, the endometritis, feeling of weight in the pelvis, backache and pain in the ovarian regions, and this occurring every month gradually becomes chronic, and so the symptoms are constant. Being a constant irritation the general system suffers, and the patient becomes a confirmed invalid.

In the treatment of these cases, if we admit the cause to be the flexion, the indication is to remove that cause, that is, render the canal straight and patulous, and to do this we have a variety of methods to choose from.

If the displacement can be easily reduced it may be held in place by a pessary during treatment, which is directed toward restoring the normal tone to the parts.

In other cases it is found that although the flexion is easily reduced, the displacement immediately returns, and the pessary instead of correcting the flexion places the uterus in retroversion. These cases may be treated in one of three ways:

(1) By wearing a stem pessary. (2) By what is known as gradual dilation, which is the passing of a series of graduated sounds from time to time which dilate the canal, and at the same time restore the uterus to its normal position; or (3) by rapid dilatation which is performed, the patient being etherized, by passing an instrument through the internal os and stretching the canal as far as may seem necessary.

This also straightens the uterus. A glass or hard rubber stem is then inserted and kept in place for two or three weeks, the patient being confined to bed during this time. Hot douches with various applications to the canal should be combined with these methods to allay the congestion in the pelvis and correct the endometritis. Together with the local treatment should be prescribed general tonic treatment, embracing hygienic rules, exercise in the open air, correcting the diet, and avoiding, as far as possible, all worry and anxiety.

Some cases are met with in which there is no appar-

ent obstruction, the sound passing easily. Here the dysmenorrhœa is explained on the ground that the endometritis causes the mucous membrane to swell to such an extent at the menstrual period that the canal is occluded. In these cases mechanical treatment is not called for, but general treatment with the local applications will affect the desired result.

The cases which I have seen at the Boston Dispensary I have not included in my table, as it is impossible to keep them under observation long enough to establish any positive deductions. Leaving those out, I find that I have seen 107 cases, 51 married and 56 single. Of the married 40 were sterile. Seventy-one out of the 107 have submitted to treatment, 37 single and 34 married, with the following results. I have divided them into four classes according to the treatment employed, that is, gradual dilatation, rapid dilatation, pessary, and general treatment.

## GRADUAL DILATATION.

	Single.	Married.	Total.
Number of cases . . . . .	9	8	17
Cured . . . . .	2	2	4
Relieved . . . . .	4	2	6
No benefit . . . . .	3	4	7

## RAPID DILATATION.

	Single.	Married.	Total.
Number of cases . . . . .	9	8	17
Cured . . . . .	6	7	13
Relieved . . . . .	1	1	2
No benefit . . . . .	2	..	2

## PESSARY.

	Single.	Married.	Total.
Number of cases . . . . .	4	8	12
Cured . . . . .	1	1	2
Relieved . . . . .	3	6	9
No benefit . . . . .	..	1	1

## GENERAL TREATMENT.

	Single.	Married.	Total.
Number of cases . . . . .	15	10	25
Cured . . . . .	2	..	2
Relieved . . . . .	6	4	10
No benefit . . . . .	7	6	13

It is thus seen that the best results have been obtained from rapid dilatation, and that is the method which I always advise, except in a few cases where the displacement can be corrected by a pessary.

A few words regarding the technique of this operation may be in place. It is by no means to be undertaken in a careless manner, but should be done with all antiseptic precautions and with the utmost gentleness. The patient being etherized, a thorough examination of the pelvis should be made to see that no contraindication exists. This being determined, she is placed in the Sims position, and a speculum being introduced into the vagina, the vagina and cervix are cleansed with a corrosive sublimate solution, 1-1000. The cervix is then held by a tenaculum, and the canal dilated by the graduated sounds until the dilator can be introduced. In introducing the sounds care must be exercised to see that they follow the canal and do not penetrate the uterine wall, an accident which has happened with fatal results. When the dilator, preferably an Ellinger's, can be introduced, the canal should be swabbed out with the corrosive solution, then the dilator is inserted with the bend forward, and the canal is dilated by gradually separating the blades. Too much force should not be used or the tissues will be torn, the object being to stretch the tissues rather than tear them. After holding the instrument in this position for a few minutes, the force should be relaxed, allowing the blades to come together, and then changing the position of the instrument, the stretching should be made in another direction. This alternate stretching should be continued until the canal is dilated sufficiently to allow the passage of a hard, straight

stem, either glass or hard rubber, which is then inserted and held in place by pledgets of cotton packed into the vagina or a pessary fitted with a cup which holds the stem in place. The stem remains in the uterine canal for two or three weeks the packing being changed every two or three days, and while the stem is worn the patient remains in bed. I have never seen any bad symptoms follow this operation except in one case, in which there was a great deal of pain referred to the lower part of the abdomen. There was no elevation of temperature, and the patient seemed perfectly well in every other way. The stem was allowed to remain, the pain being controlled by morphine, and the patient is now well of her uterine trouble, and her general health is very much improved.

## RECENT PROGRESS IN SURGERY.

BY H. L. BURRELL, M.D. AND H. W. CUSHING, M.D.

(Continued from No. 17, page 499.)

### ON CONICAL STUMP AFTER AMPUTATION IN CHILDREN WITH REFERENCE TO ITS PHYSIOLOGICAL CAUSES AND PROGNOSIS.

C. A. POWERS<sup>23</sup> records a number of instances of conicity of the stump occurring in children after amputation. In the cases which he has recorded the conicity hardly seems accidental and probably is coincident to the amputation. He says, "Certainly none can doubt that the long bones increase in length more by addition to their ends than by interstitial deposit. Take the humerus for example; there the chief point of growth is at the upper end where the epiphysal centre is first to appear and the last to become fused to the shaft. Here we have the constant ossification of the layers of cartilage which intervene between the epiphysis and the shaft. These layers of cartilage constantly grow on the one surface while they ossify on the other."

He submits the following: "Given an amputation through the humerus of a child at a point not far below this epiphysal line, the ossification of the cartilage is not interfered with and increases the length of fragments far out of proportion to the relation, in length, which the fragment itself bears to the original length of bone. The growth in the soft parts is commensurate only with their length, and less in extent than normal because of atrophy and retraction. Thus we may conceive that this constant osseous deposit in the epiphysal cartilage tends to press the end of the bone into and through the soft parts."

He submits the following propositions:

"(1) Amputation through the arm or leg in children may be followed by a conical condition of the stump, and this sequel is a probability rather than an improbability.

"(2) This conicity may be physiological and independent of inflammation or retraction of the soft parts, or the osseous deposit at the end of the bone.

"(3) The younger the child and the nearer the seat of amputation to the upper epiphysis of the limb, the greater the probability of early conicity. These factors should be considered when making prognosis.

"(4) The weight of extant authority favors flaps of excessive length, but this measure may not prevent development of the conical condition.

"(5) When the conical condition is present, the only suitable treatment consists in resection of a sufficient portion of the bone.

"(6) Successive reamputations may be required.

"(7) The above conditions may apply, but with very much less of force, to amputations through the forearm or thigh."

### THE TREATMENT OF VESICAL CALCULUS IN MALE CHILDREN.

After a careful consideration of vesical calculus in male children, Dr. J. William White<sup>24</sup> believes the following conclusions in regard to choice of operation justifiable:

(1) In every case of calculus in male children, litholapaxy, on account of ease of performance, low mortality, speedy recovery, and absence of danger of emasculation, should be the operation of predilection, division of the meatus being freely resorted to if that portion of the urethra offers an obstacle to the introduction of instruments.

(2) The lithotrite and evacuating-tube should be of a size which can be inserted into the bladder without much effort or over-distention, and great gentleness should be observed in passing these instruments.

(3) They should be withdrawn and reintroduced as seldom as possible, the stone being finely pulverized before the lithotrite is taken out at all. In seeking for or attempting to seize the stone, care should be taken to avoid such wide separation of the blades as will bring the male blade in frequent contact with the vesical neck. The crushing should invariably be done only after rotating the blades into the centre of the bladder. Every particle of the calculus dust should be evacuated.

(4) Rest in bed, milk diet, and sterilization of the urine by boric acid or salol given internally both before and after the operation are valuable adjuvants. During the operation every antiseptic precaution should be observed.

(5) The exceptional cases of calculi, which are both large and hard, may be best treated by suprapubic lithotomy, but neither unusual size nor a moderate degree of density should of itself alone be thought positively to contraindicate litholapaxy.

(6) Perineal lithotomy has now a very limited field, and should be employed chiefly in those cases of stones thought to be of small or medium size in which no lithotrite, however small, can be introduced with safety.

### GLUCK'S METHOD OF INSERTING IVORY JOINTS AS A SUBSTITUTE FOR EXCISED ONES.<sup>25</sup>

One of the most interesting methods shown at the last Berlin Congress was that by Gluck for inserting ivory joints as a substitute for excised ones. Much adverse criticism was elicited and much scepticism was the result. In one instance, however, a patient was shown with a joint capable of a motion of forty-five degrees, but the ultimate fate of the joints has not yet been determined. In the *British Medical Journal*, No. 1,550, there appears an account of Gluck's cases and the possibilities are summed up as follows:

(1) They may possibly remain there, imbedded in the tissues and, like pieces of metal, bullets, etc., give

<sup>23</sup> Medical News, May 17, 1890.

<sup>25</sup> Arch. I. Clin. Chir., 1890, xii, 187; also, Annals of Surgery, 1890, vol. xii, p. 256.

rise to no further trouble. Should such be the case with a joint, it is clear that, even if the patient walked well at first, owing to the plugs being sufficiently firmly united to the living bone to permit of it, the joint must after a while wear out, become broken and require to be repaired, thus necessitating a second operation. It is, however, extremely unlikely that any such result would occur. Pathology and practical experience have both taught us, that bone or ivory when it is employed for the union of bony parts, only plays a temporary part in their restoration, and is, after a time, longer or shorter, as the case may be, completely absorbed. Gluck's own case, just mentioned, shows how rapidly such absorption can take place; in fourteen weeks after he had completed his operation on the humerus, the bone which was extracted was much eroded all over its surface. If a joint is to be inserted, which would be capable of performing its functions for any length of time, it must be constructed of metal, or of some material which will resist those powers of absorption which are the property of all animal tissues.

(2) These introduced pieces of ivory may prove a source of so much irritation that the animal tissues will not erode them, and they will then speedily become loosened from their surroundings and form a sequestrum, which if not removed, will only remain as a source of irritation, and will, after some slight injury, give rise to suppuration and make its own exit *volens volens*. This is practically what would have happened to Gluck's myeloid sarcoma of the humerus case had the ivory plug not been removed by the professor as soon as it had ceased to be fixed to the surrounding tissue.

(3) The irritation of the foreign body will set up an overgrowth of bone in the neighborhood, and thus a joint which is at first movable will, provided much periosteum remains near it, be slowly enveloped in a new bone formation, and have its power of movement gradually checked and eventually brought to a complete standstill by the masses of bones, which advancing from both of the long bones to which it is attached, will at length produce a stiff joint and enclose the ivory apparatus. Complete absorption or necrosis of the ivory joint will then only be a matter of time.

Thus it would seem that surgery can hope for but little aid in this plan of treatment, except in so far as it aids us in promoting the union of bones, or in preserving temporarily the length of a limb of which considerable portions of bone have been destroyed, thus giving time for the periosteum that remains to supply a new bone equal in dimensions to the one that has been removed.

We shall await with interest the future history of these cases on which Gluck has tried his ingenious plan of bone-implantation, and we shall indeed be surprised if any useful improvement remains three years after the insertion of their ivory joints.

#### ON EXCISION OF THE SUPERIOR MAXILLA.

From an interesting study of 250 cases of excision of the superior maxilla, Joseph D. Bryant,<sup>85</sup> has deduced the following conclusions:

(1) That excision of the superior maxilla is not a dangerous operation.

(2) That, contrary to general belief, excision of both superior maxilla is not a specially dangerous procedure.

(3) That, while dangerous hemorrhage is not fre-

quent in the operation, still its effects are to be feared more than other results of the operation itself.

(4) That removal of the upper jaw for the cure of bony and fibrous tumors, and the removal of nasopharyngeal polypi is attended frequently with dangerous and fatal hemorrhage.

(5) That ligation of one or both *external* carotids is a safe and commendable procedure when dangerous hemorrhage is apprehended, as the result of operation on the area of their distribution.

(6) That ligation of one or both of these arteries may delay the return, and hinder the progress of morbid growth, if it be developing in tissues supplied with blood by those vessels.

(7) That, all things being equal, ligation of the *common* carotid for the purpose of controlling the circulation of the external is unwise, unsurgical and unwarrantable.

(8) That complete removals are five times as fatal as incomplete removals of single superior maxilla; irrespective of the nature of the disease and of the side removed.

#### RESECTION OF THE KNEE IN ADULTS.

O. Schluter has published<sup>87</sup> the results of his study of the operation of the resection of the knee for tuberculous disease. Among other interesting data that relating to the ultimate result of this operation is at present especially interesting and valuable. He has succeeded in obtaining information from 70 out of 80 cases respecting the final results. Forty-four patients were found completely cured; 20 had died, sixteen within two years following the operation. By far the greater part (15) resulted from tuberculosis. The ages of the patients investigated varied from twenty to sixty, a majority being between twenty to forty years. Schluter concludes that resection of the knee for tuberculosis in adults results in a useful limb in sixty-four per cent of cases in about six months, but that as time increases, this percentage is somewhat lowered; that the results are not so good as from operations on younger persons; that the resulting somewhat shortened extremity gives a firm support and is preferable to an amputation. The recovery from the operation is usually uneventful, but primary union is rare. The average interval elapsing from the operation to the commencement of the use of the limb is stated as two months.

#### UNUNITED FRACTURES.

Sommer<sup>88</sup> has collected from the records of the Zurich Klinik, 16 cases of ununited fractures. The time was from April 1, 1881, to January 1, 1888. Six cases occurred while the patients were under treatment at the hospital for recent injuries. These were from 489 cases of fresh fractures, among which were also 16 cases of delayed union where comminution, necrosis and suppuration were the causes. The remaining eight cases were admitted for already established pseudo-arthritis. The site of lesion occurred twice in the shaft of the femur, four times in the tibia, three times in the humerus, twice in the forearm, and three times in the radius. Three patients were women, and eleven men. Ages sixteen to seventy years.

Etiology: Not from constitutional conditions except perhaps in one case of anemia from excessive hemorrhage combined with severe diarrhea. The local conditions seemed to be more important causes of non-

<sup>85</sup> *Annals of Surgery*, May, 1890, p. 305.

<sup>87</sup> *Deutsch. Zeitschr. f. Chir.*, 1890, XXX, 4-5, p. 285.

<sup>88</sup> *Beitr. z. Klin. Chir.*, 1890, VI, 2, p. 363.

union; very oblique fractures with tendency to displacement, permanent interposition between fragments of soft parts, insufficient fixation of fragments, etc. The cases which were to be ununited fractures always showed no tendency to union, never merely a yielding of fragment. The results showed great impairment of function. Callus formation was entirely absent in nine; in the other five a mass of connective tissue united the fragments. The duration of these cases from time of injury to treatment was as follows: six within six months; seven, from seven to eleven and one-quarter months; one, two and one-half years. At the operation, isolated cicatrized ends of fragments were found in eight cases; in three others, a fibrous union of fragments. No case of nearthrosis was reported. Mechanical treatment was unsuccessful except in one case, and here the substance between the fragments was subcutaneously ruptured.

The operative treatment: In two cases, nails in the connective tissue band of union (Malgaigne); once, no reaction; once, slight fever, marked local pain, subsequent consolidation; in four cases, the Dieffenbach method, with the modification of cutting off the ivory pegs at the surface of the bone and leaving them permanently *in situ* (Bidder); resection of ends of fragments in eight cases; six times with silver-wire suture. Seven successful results. One case remained unhealed and refused a second operation. In one case, a femur, the upper fragment was cut wedge-shaped, and inserted in the central cavity of the lower.

In this connection Munk's<sup>29</sup> brochure is interesting, in which he reports the successful treatment of five cases (one a fresh compound fracture, four cases of pseudo-arthritis), by ivory plugs placed in the medullary canals, — one humerus, one femur and three tibiae. Three were discharged with firm union; two with union, but still under observation at time of publication. He attributes the result to the fixation of the fragments by the plug, and to the production of osteoplastic inflammation by its presence. The method seems to him to be especially valuable where there is a separation of fragment ends by loss from comminution or other causes, the plug then forming a firm bridge and being the nucleus for callus formation. This fixation is valuable in fresh oblique fractures of the leg. Munk exposes the ends of the fragments, and then fits the ivory plug into the canal, which is previously bored out, if necessary, to admit it. The technique by which the ivory plug is prepared or sterilized is not stated, but the aseptic healing of the wound is considered of vital importance. The plug is not absorbed, but remains indefinitely.

(To be continued.)

The *Journal of the American Medical Association* (of April 11th) prints a long letter from a correspondent, suggesting certain improvements in that periodical, and giving his reasons in full. He says, in the first place, that "It should be printed on plain and not on glazed paper, which from its reflection, dazzles the eye, irritates the optic nerves, muscles and lobes, brain and mind, and sympathetically other parts of the system, thus impairing the sight, causing eye-strain with spasm and twitching of muscles, ocular and cerebral hyperæmia, dizziness, headache, neuralgia, melancholy, petulance, irascibility, and other disorders of the physical, mental and moral nature, more or less serious."

## Clinical Department.

### INJURY TO THE EAR FROM A PIECE OF WOOD.<sup>1</sup>

BY FREDERICK L. JACK, M.D.

The following brief clinical history of a case of injury to the ear is presented to the Society, chiefly because the case is a very unusual one.

A. D., five years of age, was brought to the Massachusetts Charitable Eye and Ear Infirmary, October 1, 1890, during the service of Dr. Green, to obtain relief from intense pain in the right ear. According to his mother's statement, the cause of the trouble at that time dated back three months. The patient was seen running away from his playmates with a paper wind mill on a stick protruding from the mouth. He stumbled, fell and was carried across the street to his home, bleeding from the mouth, nose and right ear. In the evening the ear became painful. On the following night the pain was intense and extended over the right side of the head. On the next morning a discharge from the ear was noticed.

Since then the pain and otorrhœa had continued. Five weeks after the accident pus began to flow from a spontaneous opening over the tip of the mastoid process. A few days later facial paralysis was noticed.

I saw the patient on October 1st, when the condition was as follows: The supra- and retro-auricular regions decidedly swollen. Complete facial paralysis. External auditory meatus filled with granulations. Otorrhœa profuse, also free discharge of pus from the opening over the mastoid. Hearing greatly impaired. Tuning-fork placed on vertex heard loudest in the right ear. Examination of the throat negative. Pain for the last ten nights had been very severe, and he was considerably emaciated. Under ether, I enlarged the post-aural opening, and with the probe was unable to detect dead bone at the depth of nearly one inch and a half along the posterior wall of the external canal. The granulations in the external meatus were removed by means of the snare and forceps. The bleeding rendered a view of the drum membrane impossible, but with the probe what was supposed to be a sequestrum was detected at the bottom of the canal. Efforts to extract it with forceps failed, but it was easily brought away by means of a hook. The object proved to be a piece of wood, in appearance nearly like one-half of a common brimstone match, which was forced in some way through the membrane of Shrapnel at the time of the fall on the sidewalk three months before.

The patient remained under observation for three weeks, during which time there was no pain, and the ear healed rapidly. On October 20th there was no discharge from the ear, or from the opening over the mastoid. On inspection, the external canal was perfectly free from granulations, and the membrane in a cicatricial condition. Hearing for watch twenty inches. Dr. Walton kindly saw the case, and reported "pretty nearly complete facial paralysis with degeneration reaction."

A TENNESSEE doctor is credited with delivering two children with a pair of shoemaker's pincers, using the curved handles as obstetric forceps.

## Therapeutic Department.

### THE INTERNAL USE OF THE SIMPLE ASTRINGENTS.

BY M. A. WALKER, M.D.

PURE astringents are agents which cause contraction of living tissues, especially the circulatory channels, and have no appreciable effect on the action of the heart.

All, of course, will admit that this definition is correct, and that it represents the effect normally produced by their exhibition. So we will proceed to look a little more closely at their action on the blood-supply and their therapeutics when exhibited internally.

The heart, as we know, under ordinary circumstances and normal conditions, contracts from seventy to eighty times each minute, each contraction completely emptying the ventricles. The capacity of the left ventricle being about five ounces, then in each minute there passes into the aorta and consequently through the whole systemic and pulmonary circulations from 350 to 400 ounces of blood. Now it is evident that without change either in the frequency of the heart's contractions, or its capacity, the same amount of blood will, of necessity, be forced into the aorta and through the whole body — no matter what may be the size of the aorta or smaller vessels — in the same length of time.

On the administration of a substance which causes general constriction of the vessels without changing the amount of blood forced into them, the intravascular tension must be increased, and consequently the rapidity of the current, proportionate with the constriction. So that any vessel or series of vessels being selected for examination, it will be found that just as much blood passed through them in the same time, as passed through them before such administration.

Hence, in endeavoring to control hemorrhage by the internal administration of the simple astringents, we only contract the vessels from which the blood is flowing, at the expense of causing a proportionate increase of tension, and consequently do not at all affect the rapidity of the loss of blood. There is, of course, a similar objection to the use of these substances in controlling inflammations.

Therefore, do not let us use astringents, given *per os*, as any aid to the treatment of hemoptysis, erysipelas, or any other conditions where we desire to cause a decrease of the supply of blood to the part.

THE RUSSIAN INSTITUTE OF EXPERIMENTAL MEDICINE, founded in St. Petersburg by Prince Alexander Petrovitch, of Oldenburg, at a personal cost of over \$100,000, was formally opened and handed over to the Imperial Government on December 20, 1890. The ceremony was attended by the ambassadors, several members of the Czar's family, and by M. Chamberland, representing M. Pasteur; Dr. Pfuhl, representing Professor Robert Koch; and Mr. Watson Cheyne, representing Sir Joseph Lister. The Prince of Oldenburg was appointed Governor of the Institute; the three delegates made brief addresses; and the proceedings ended with an entertainment in the Oldenburg palace.

## Reports of Societies.

### AMERICAN MEDICAL ASSOCIATION.

THE FORTY-SECOND ANNUAL MEETING, HELD AT WASHINGTON, D. C., MAY 5-8, 1891.

#### GENERAL SESSION. — FIRST DAY.

(Continued from No. 20, page 490.)

AGAIN, as a diagnostic symptom, the touch revealed a great deal. In cancer the nodular form of the mass was more apparent than in any other trouble. In syphilis, the induration was more even and extended with more regularity, and after a time was of a fibrous character and was so indicated to the touch. In simple ulceration, the stricture was apt to be annular. As a method of diagnosis, he objected to the use of rectal bougies, either metal, soft or hard rubber, to which so many authors called attention. They were exceedingly dangerous and accomplished no earthly good.

In dealing with the question of treatment, the author said that he should adhere in the strictest sense to the pathological condition, namely, a stricture. The methods practised to-day for treating stricture of the rectum were: (1) Dilatation. (2) Incision. (3) Electrolysis and cauterage. (4) Excision. (5) Colotomy. Of course, under the division he has made, general treatment was ruled out.

The gradual dilatation of stricture was objectionable, for the reason that by this form of repeated irritation, more plasma was thrown out and the strictured surface increased. It may be true that some temporary relief was afforded, but upon the contraction of the tissue, we had lost more than we have gained. He did not hold the view that by the passing of bougies through the strictured surface, absorption of the tissue was caused, but believed that the converse was true. Why forcible division was seldom applicable in these cases he could not understand. If a fibrous stricture existed, forcible division was the best method.

He was very partial to incision or incisions for the relief of stricture of the rectum. Of the two operations recommended, internal and external, posterior, linear, proctotomy, he preferred the internal. It was urged for the external, which consisted of not only going through the strictured surface, but also in dividing the sphincter muscle, that it was all important to get the necessary drainage. He did not think so, and if he did, he believed the ill effects of dividing the sphincters outweighed the matter of drainage. His plan was to introduce a three or four valve speculum, and after dilating sufficiently for the purpose, a long sharp knife was used to divide the constrictions; of fibrous tissue, down to a healthy base, — not only in the median line, but in several places around the circumference of the gut. He then placed a tampon, through which was inserted a metallic tube for drainage and the escape of gases. This tampon was aseptic, and usually dusted with powdered persulphate of iron. On the fourth day it was removed and the rectum was irrigated with a mercuric solution. If the operation was done effectually, he had never seen the necessity of employing the bougies afterward, for the purpose of dilatation.

*Excision.* — He thought a better term to employ here would be extirpation. Excision of a stricture of the rectum conveyed but little idea of the operation.

He could not appreciate the idea of excising a benign stricture, there were methods so much simpler in their nature, for the relief of these conditions. Extirpation of the rectum for malignant disease was an ideal operation. It was an axiom in surgery that in operating for cancer, the whole growth must be removed, together with the glands that were involved. Let them take this axiom as a guide in rectal surgery. If the growth extended beyond the point where it was prudent to operate, it was best not to attempt its removal, except, perhaps, for total obstruction, not with any idea of cure.

Kraske's operation was admirably suited to cancerous stricture. It consisted in resecting the diseased part, through an opening made at the left side of the sacrum. This operation was only applicable in a certain class of cases. If the sigmoid flexure was involved, it would be of no use. According to this method, the soft parts were divided in the median line from the second sacral vertebra to the anus. The muscular attachments to the sacrum were divided as far as the edge of the opening on the left side. The coccyx was removed, the attachments of the two sacro-sciatic ligaments to the sacrum cut, and the soft parts drawn to the left side. If still more room was necessary, it might be gained by removing a part of the lower left side of the sacrum. If the bone was divided on a line, beginning on the left edge, at the level of the three posterior sacral foramen, and running in a curve concave to the left, through the lower border of the three posterior sacral foramina and through the fourth to the left lower border of the sacrum, the more important nerves were not injured and the sacral canal was not opened. In this way, the lower part of the rectum, as far as the sigmoid flexure, might be regulated. It would be found in this operation, the dissection was a very difficult one.

He was more and more persuaded that where there was a possibility of removing the entire malignant growth from the rectum, excision was far preferable to colotomy. Excision would remove the disease, thereby leaving some grounds to hope that it would not reappear. By colotomy we simply palliated the symptoms, leaving the disease in its ravages. As he had said in this article, pain was within the growth itself, by the involvement of the nerves. Surely colotomy could not relieve it. It was likely true that the faeces passing over the growth might irritate it to a certain extent, but his experience had taught him that if the sphincter muscles were not involved, there was but little pain, and if they were involved, scraping the mass out, according to the Germans, would relieve it, equally as well as colotomy would. Again, it must be admitted that after colotomy was done, there was no absolute certainty that some of the faeces would not pass down into the rectum.

Secondly, that it prevented obstruction. It would be admitted that the greater number of cancers were located in the lower or fixed part of the rectum. It was a recognized fact, too, that total obstruction from fecal impaction rarely took place; because it was the disposition of malignant tissue to break down after a certain stage. But suppose it did not, and a stricture total, if you please, resulted; to cut through it, divide it, or resect it, would be better than to do colotomy. The first two would promise equally as much, and the last much more. He had never seen a total obstruction by faeces in a cancerous stricture. He had known

total obstruction to occur by the closure of a stricture. We had means of eradicating this by the three methods mentioned. They were much simpler than colotomy, why not do them?

Thirdly, that it retarded the growth of cancerous disease. Neither could he subscribe to this proposition. How the establishment of an artificial opening in the loin or groin materially retards the growth in the rectum, he could not understand. He knew that it was used as an argument that the stoppage of the faeces over the growth, would, to a degree, stop the growth. This was utterly fallacious. The cancer persists in its progressive course of infiltration, ulceration, etc., with as much rapidity after colotomy was performed. Correct statistics of the conditions would verify his statement. Admitting that there was truth in the assertion, patients who suffered with cancer to that degree, or extent, requiring colotomy, were not anxious to have their lives prolonged. As a last argument, it was said that colotomy substitutes a painless death for one of great agony. This statement could not be borne out by facts. Patients who had malignant disease of the rectum usually died of a low and gradual form of peritonitis. He had witnessed a number of such deaths, and they were usually painless. If he were asked, when was colotomy justified in cancer of the rectum, he would answer, not at all. But if there was total obstruction of the sigmoid flexure from a cancerous mass, and if for any special reason we wished to prolong life, then colotomy would be justifiable.

#### A MEDICAL CABINET OFFICER.

To those who read between the lines there was no more important decision made in the general session than the adoption of a resolution which pledged the Association to memorialize Congress as to the creation of the office of a Medical Secretary whose business it shall be, by means of organized sources of information and communication, to keep in touch with all the broader medical questions and matters throughout the country. It is expected that such a cabinet officer, by his affiliation with the central government, will further those legislative enactments, in respect of medical education and public hygiene, which are, by the majority of the profession, now deemed essential to the progress of modern medicine and the maintenance of public health.

By an overwhelming vote it was decided to keep the Association's Journal in Chicago. No change of editorship or of management was made.

#### SURGICAL SECTION. — FIRST DAY.

The Chairman, T. A. McGRAW, M.D., of Detroit, opened the Section by reading an address on

#### THE USE OF THE ELASTIC LIGATURE IN THE SURGERY OF THE INTESTINE.

Intestinal surgery has recently made great advances, owing largely to the work of Senn on intestinal anastomosis. This operation is indicated in chronic stenosis and acute obstruction of the intestine, and sometimes in cases of false anus and fecal fistula. To be able to operate rapidly is always an advantage in intestinal surgery. Senn's operation was a time-saving one. In order to save still more time, and also to escape the danger of the intestinal contents escaping into the peritoneal cavity, the author has adopted the

elastic ligature. The rubber suture is of larger calibre than the needle which carries it, being trimmed down to fill the eye, so that the hole made in the gut is completely filled. The loops of intestines to be united are first joined by a Lembert suture, close to which row of sutures the rubber ligature is passed through as near as possible at right angles to the surface, and carried lengthwise of the bowel for an inch to an inch and a half, then out again and into the opposite section of gut in the same way. The two free ends are then pulled taut and tied together securely. The Lembert suture is then continued, completely enclosing the elastic suture, which is left to slowly cut its way through the opposing intestinal walls. By experiment it was found that in three days anastomosis had been established sufficiently to admit water. In no case has the presence of the ligature caused pain.

This method is of course only applicable to cases where an anastomosis established four days after operation is requisite. Where immediate establishment of the continuity of the gut is required some other operation must be chosen. On dogs the author has been able to do the operation with great rapidity. In a man with cancer of the pylorus a union was made between the stomach and small intestine, the operation, after exposing the stomach, lasting only eleven minutes, and being completely successful.

Dr. T. G. MORTON, Philadelphia, read a paper on

#### APPENDICITIS AND PERICÆCAL INFLAMMATIONS.

with notes of cases illustrating special difficulty in diagnosis. If an operation is to be done, it must be done early; and if there is any sign of disease of the appendix, it should be removed. The calibre of the appendix is not as great as it is often supposed to be; in fact, it is generally collapsed, and admits only a probe. It is seldom joined to the cæcum at its lowest point. The division of disease of the appendix into groups, and the indications for operation were given, and several cases reported.

In the discussion Dr. McGRAY, of Atlanta, said that in thirty-five per cent. of the autopsies after deaths from all causes, he had found in the appendix evidences of previous disease.

Dr. H. O. MARCY, of Boston, read a paper on

#### THE SCIENTIFIC RATIONALE OF MODERN WOUND TREATMENT.

The subject of antisepsis was discussed, and reference made to the works of Jeffries Wyman, and later of Lister. The position of Tate was criticised, and the recent paper of J. William White noticed.

Dr. CHRISTIAN FENGER, of Chicago, read a paper on

#### A NEW OPERATION FOR HÆMELIP.

and showed illustrations. There is always a deficiency of tissue, and none should be sacrificed. His incisions are linear; and deep-tension sutures are an important part of the operation, but these sutures should not go through the mucous membrane.

Dr. AUGUSTUS P. CLARKE, of Cambridge, Mass., read a paper on

#### SOME POINTS IN THE SURGICAL TREATMENT FOR THE RADICAL CURE OF HERNIA.

Everything connected with the operation should be aseptic. The sutures require special care. They

should be animal tendon or catgut, not silk, and must be specially prepared to insure asepsis. The obliquity of the inguinal canal should be maintained. Drainage should not be used.

#### SECOND DAY.

The first paper was by F. McF. GASTON, M.D., of Atlanta, on

#### TRAUMATISM OF THE CHEST.

All penetrating wounds should be closed, even if large and even if it will be subsequently necessary to reopen the chest. During the war sixty-five per cent. of the penetrating wounds of the chest were fatal.

Papers were also read by Dr. W. C. WILE, of Danbury, Conn., on "The Surgical Uses of Aristol"; Dr. M. PRICE, of Philadelphia, on "Peritonitis from a Surgical Standpoint"; Dr. B. A. WATSON, of Jersey City, on the "Relation of Concussion of the Brain and Spinal Cord to Inflammatory and other Morbid Changes in these Organs"; and HERMAN MYNTER, of Buffalo, on "Is Early Excision or Conservative Treatment in Coxitis Indicated?"

#### SECTION ON PRACTICE OF MEDICINE AND PHYSIOLOGY.—FIRST DAY.

The Chairman, VICTOR C. VAUGHAN, M.D., opened the Section with an address on

#### THE GROWING IMPORTANCE OF CHEMICAL STUDIES IN MEDICAL EDUCATION AND IN MEDICAL RESEARCH.

With the advance of scientific work in physiology and chemistry much has been learnt of the different constituents of the human body by special workers, and this knowledge should form a part of medical education, in order that therapeutics founded on error should be thrown aside, and rational treatment take the place of empiricism. The author described the chemistry and physiology of the animal cell at some length, and also considered in a concise and interesting review the chemical and physiological changes in disease.

Special reference was made to uræmia, and the investigations of Schröder quoted. Another direction in which scientific research should help practical medicine is in the physiology and chemistry of digestion, and the results of recent investigations were given.

Dr. J. P. CONNELLY, of Williamsport, Pa., reported a case of

#### FATTY URINE ACCOMPANYING AN ABSCESS IN THE RIGHT ILIAC FOSSÆ.

A colored woman, after childbirth had chills at irregular intervals, with pain and a deep-seated tumor in the right iliac fossæ. The urine was covered with an oily substance like olive oil, but which became of a tallowy consistency on cooling. Three and a half ounces were passed daily for some days, when there was a sudden discharge of pus with the urine, and the fat immediately and permanently disappeared.

Dr. J. W. CARHART, of Lampasas, Texas, read a paper on the

#### USE OF DIGITALIS IN THE FIRST AND SECOND STAGES OF PNEUMONIA.

Digitalis should not be given at this time, especially in broncho-pneumonia of children. The frequent use

of this drug may be the cause for the high death-rate often reported from this disease.

DR. J. S. JACKSON, of Norfolk, read a paper on  
TUBERCULIN, ITS VALUE AS A SCIENTIFIC DISCOVERY,

apart from its therapeutic importance, together with a consideration of the most rational mode of employing the principle involved in it.

DR. J. S. GEDDINGS, of the Marine-Hospital Service, reported the results obtained by him with tuberculin in twelve cases of phthisis and one of lupus. These cases have already been described in the abstracts of the Marine-Hospital Bureau. The author concludes that our knowledge of tuberculin is still in its infancy, that the cases which can be improved by it are limited in number, and are only among those in whom the tubercular process is slight. It is dangerous in laryngeal and hæmorrhagic cases.

DR. GEORGE E. FELL, of Buffalo, read a paper on  
TWO ADDITIONAL INSTRUCTIVE CASES OF FORCED RESPIRATION,  
and showed an apparatus.

THE PATHOLOGY AND TREATMENT OF PHTHISIS  
was the title of a paper read by DR. ASA F. PATTEE, of Boston.

#### SECOND DAY.

DR. J. W. SMALL, of New York, read a paper on  
THE TREATMENT OF THE FIRST STAGE OF PNEUMONIA.

He recommended heat and friction to the extremities and hot poultices to the chest. Internally Dover's powder and nitrate of potash with, in some cases, fifteen grains of antipyrine.

DR. F. W. GOODELL, of Bennington, Vt., read a paper on

SOME OF THE REMOTE EFFECTS OF INJURY TO THE  
BRAIN IN DELIVERY,

in which he found a connection between obstetric positions and right handedness.

DR. J. LEWIS SMITH, of New York, made some interesting remarks on

RECENT CONTRIBUTIONS TO THE KNOWLEDGE OF  
DIPHTHERIA.

True diphtheria is the result of the Klebs-Löffler bacillus. Other micro-organisms may produce similar changes, which may be classified as pseudo-diphtheria. Among these is the diphtheritic throat complicating scarlet fever. The diagnosis of true diphtheria can always be made by the discovery of the specific bacteria. The contagion of the disease and vitality of the bacillus were discussed.

The Chairman had been able to find the Klebs-Löffler bacillus in two epidemics, but in a third, equally fatal, he could not find it. He therefore thought that the term pseudo-diphtheria should not be understood to refer to a disease which is always mild and not contagious.

Papers were also read by DR. JAMES J. PUTNAM, of Boston, on "The Character of the Evidence Respecting Arsenic as a Domestic Poison"; DR. L. WOLF, of Philadelphia, on "The Use of Naphthalin in Typhoid Fever"; DR. B. M. GRIFFIN, of Springfield, Ill., on "Antiseptic Treatment and Liquid Diet in Typhoid Fever."

(To be continued.)

## BOSTON SOCIETY FOR MEDICAL OBSERVATION.

T. F. SHERMAN, M.D., SECRETARY.

REGULAR Meeting, Monday, February 2, 1891, DR. J. S. GREENE in the Chair.

DR. J. B. SWIFT read a paper on

SOME OBSERVATIONS ON ANTEFLEXION OF THE  
UTERUS.<sup>1</sup>

DR. DAVENPORT: Dr. Swift has covered the ground of the subject so well that very little remains to be said either in the way of criticism or of amplification. Without being able to speak otherwise than from general impressions, I should say that my experience as regards the value of the various operative measures and the various forms of treatment would correspond very closely with that of Dr. Swift. Certainly I have grown to distrust the value of pessaries more and more in this condition with each year of practice. There are comparatively few women, I think, who would hesitate to choose an operation which promises as much as this does, and which is in itself so short an affair, to the prospect of wearing a pessary for months and it may be for years. This is especially true if, as is very often the case, they are married women and come quite as much for sterility as for the relief of the dysmenorrhœa. In these cases a pessary promises very little, whereas rapid dilatation, and the keeping of the canal patulous by means of the plug, does hold out a certain chance for the relief of the sterility as well as of the dysmenorrhœa. Where a pessary is used I think that the so-called antelexion pessaries will often fail to give the necessary relief, and I have found that oftentimes a pessary devised and intended more particularly for mild forms of prolapse, will accomplish quite as much as those which are intended especially for antelexion. This I explain with the idea that after the long continuance of the flexion with its consequent congestion there is a sagging of the uterus as a whole, which is relieved by the upward pressure of the pessary, and in that way there is relief of the symptoms. Some of these cases, especially of antelexion of the body, are not accompanied by dysmenorrhœa, but the principal symptoms are referable to the bladder. In such cases a pessary will often accomplish more than dilatation. The symptoms seem to be referable to the increased weight of the heavy uterus, especially of the fundus, on the bladder; and raising it out of the pelvis a little will relieve the bladder symptoms.

Gradual dilatation I think, as a rule, should precede the rapid dilatation under ether, for this reason, that a certain number of cases, as Dr. Swift's paper has shown, will not be relieved by dilatation. The difficulty is not due to mechanical obstruction, but possibly to an ovarian influence or some obscure condition which has nothing to do with the flexion. If in these cases just before the menstrual period so much dilatation is practised with graduated sounds as can be done without causing the patient too much pain, the effect can be watched in the coming menstruation; if relief is given it is fair to presume that a more thorough operation under ether, and the subsequent keeping of the canal patulous, will be of benefit. If, however, as is sometimes the case, the milder dilatation fails to give any relief, I should advise other measures, for a

<sup>1</sup> See page 601 of the Journal.

while at least, before resorting to the operation of division or rapid dilatation. The latter operation has in the large majority of cases in my practice superseded that of the incision of the cervix which formerly was practised. There are a few cases in which that might still be advocated, where both body and neck are very sharply anteflexed, and it is desired to straighten the canal by means of an incision backward through the cervix almost to the vaginal junction. But these cases are comparatively rare. The operation is a more hazardous one than that of dilatation, and it is only in the exceptional cases that it would be advisable.

DR. TEMPLE: I should like to ask the reader in relation to dilating the uterus. In a recent article in the *Obstetrical Journal* the author lays special stress on the dilatation of the canal in all directions, allowing the dilators to remain in one position a certain length of time, and then changing so as to get a uniform dilatation rather than in one direction only.

DR. SWIFT: I spoke about changing the direction of the dilatation, and one advantage of the gradual method is that very thing. The dilators being round, stretch the canal in all directions equally.

DR. C. M. GREEN: I should like to ask Dr. Swift if he has had cases of septicæmia after any of these methods?

DR. SWIFT: I have not.

DR. J. O. GREEN reported

#### A CASE OF ABSCESS OF THE BRAIN WITH CHRONIC MIDDLE EAR DISEASE.<sup>2</sup>

DR. INGALLS: Was there an examination with the ophthalmoscope?

DR. GREEN: There was not. I asked her about her vision, but no good opportunity occurred for a day or two, and the final result came so rapidly that no examination was made.

DR. SPEAR: I have very little to say in regard to the subject of brain abscess, not having had any experience with such cases, although the aurist is constantly on the lookout for such cases, for the reason that so many brilliant results have been obtained by operation. I was thinking of the circumstances by which Dr. Green came to see this case, and that if he had been called later it certainly would have been out of his field unless he considered the treatment of the perforation of the tympanum. Of course he would not have been called upon for that state of affairs in the brain. Dr. Green speaks of there being no symptoms whatever. I should like to ask if there was no peripheral irritation of the muscles of the body by which one might be guided in the localization?

DR. GREEN: There was not the slightest.

DR. JACK: Did I understand Dr. Green to say that the middle ear entirely cleared up?

DR. GREEN: Absolutely. The mucous membrane became perfectly pale and natural, and there was absolutely no discharge.

DR. JACK: I can say nothing to throw light on an abscess occurring in that region. I have noticed the fact that chronic suppurative inflammations of the middle ear have cleared up and the patient been discharged as convalescent or cured, and once in a while he has after four or five weeks a very sharp inflammation in the mastoid and no inflammation in the middle ear.

DR. SHERMAN: What symptoms does Dr. Green rely upon in making the diagnosis of mastoid inflammation?

DR. GREEN: The history of the onset, or previous otorrhea, and a tender bone which continues some time, would be the chief ones. Then, if you get extension of the inflammation, you get symptoms in the direction in which extension occurred, external œdema, subdural abscess.

In reply to the question, How frequent is middle ear trouble the result of the nasal douche? Dr. J. O. Green said that he thought it occurred very often; he certainly saw many cases in which tympanic inflammation supervened so directly upon the use of the douche that not only he, but the patients themselves referred the ear disease to the douche. He, himself, was unwilling to use any solid mass of fluid in the nose except by pouring it into the nostrils with the head tipped back; he did not like to use any force whatever. Even snuffing the fluid up was not unaccompanied by danger to the ears; he had seen cases of middle ear inflammation produced by this method. Atomization and pouring the fluid in with the head tipped back was the only methods he was in the habit of using.

In diphtheria, with the abundant and infecting discharge, there was certainly strong indications for the douche or syringe, for cleansing and disinfecting, but he was satisfied from experience in the diphtheria wards of the City Hospital that the danger to the ears was too great to justify the use of force. Some three years ago his attention was particularly directed to this point, but unfortunately statistics were not kept. At that time nasal diphtheria was treated by the post-nasal syringe, and there were then a much greater number of, and more serious, tympanic inflammations than he has ever seen in those wards; in the next service the post-nasal service was given up, and the tympanic inflammations almost ceased to appear.

He is told by the house-officers that now neither syringe nor douche is used, and it certainly is the exception for him to be called into those wards. He thought that if attention was directed to using a good antiseptic oil or vaseline for softening the discharges and then a cleansing fluid in the method spoken of, fully as much could be accomplished as by douche or syringe and without the irritation to the patient which those instruments produced.

DR. F. L. JACK reported a case of

#### INJURY TO THE EAR FROM A PIECE OF WOOD.<sup>3</sup>

DR. INGALLS: I did not quite understand the precise locality of the bit of wood.

DR. JACK: At the time it was extracted it was clouded by the swellings and granulations in the canal so that it was impossible to precisely locate it. In a few days after the swelling had gone down, I could see the point of entrance and it seemed to be in the upper part of the membrane of the canal of Shrapnell.

DR. DAVENPORT: Was this driven in through the ear?

DR. JACK: I don't see how that is possible. I have no means of knowing how it got there. I questioned him as to whether the wind-mill was in the ear when he fell and he said no. I examined the throat but found nothing.

<sup>2</sup> See page 503 of the Journal.

<sup>3</sup> See page 508 of the Journal.

## Recent Literature.

*Saunders' Question Compend, No. 2. Essentials of Surgery, together with a Full Description of the Handkerchief and Roller Bandage: Arranged in the Form of Questions and Answers prepared especially for Students of Medicine.* By EDWARD MARTIN, A.M., M.D., Instructor in Operative Surgery, University of Pennsylvania; Surgeon to the Howard Hospital; Assistant Surgeon to the University Hospital. Illustrated. Fourth Edition, revised and enlarged by an Appendix. Philadelphia: W. B. Saunders. 1891.

This manual, which made its appearance two years ago, has already run through two editions, which is sufficient proof that the author's effort has been thoroughly appreciated. It was written to assist the student, but it will be of undoubted use to many practitioners, containing as it does the essence of surgical work; and with the addition of the appendix of several hundred prescriptions, which will be found useful in surgical practice, the work has been added to in value.

*Transactions of the American Orthopedic Association.* Third Session. Vol. II, pp. 296. Philadelphia: Published by the Association. 1889.

This volume fully sustains the standard established by its predecessor. It presents in a neat, compact form the report of the third session of the American Orthopedic Association held at Boston, Mass., in September, 1889. The appendix to the president's address is a valuable and extensive bibliography of American orthopedic surgery prior to 1860. A greater part of the volume consists of the publication in full of the various medical papers read at the meeting. These are all of value and interest; some relating to original work especially so. The last is too long to enumerate in detail. This is also unnecessary since a majority of them have already been published *in toto*. The attention and interest of the Association was principally devoted to the investigation and discussion of hip disease, especially with reference to treatment. The report of the general discussion (page 190) following this series of papers is quite interesting. The Association is to be congratulated on its work, and its report deserves a careful perusal.

*Clinical Lectures on Varicose Veins of the Lower Extremities.* By WILLIAM H. BENNETT, F.R.C.S., Surgeon to St. George's Hospital; Lecturer on Clinical Surgery and on Anatomy in St. George's Hospital Medical School; Member of the Board of Examiners, Royal College of Surgeons of England, with Three Plates. London and New York: Longmans, Green & Co. All Rights Reserved.

These lectures, which formerly appeared in the *Lancet* now appear in book form, and are a valuable contribution to the literature on the subject. The author has taken up systematically the various conditions under which varix is liable to form; the probable causes; complications; diagnosis of varix in its incipient stages; the management of ordinary cases of varix, without operation and with operation; the details of operation; and the prognosis in the respective conditions. It is a monograph on varicose veins which a practitioner could turn to at any time, and derive a great many practical hints in reference to the causation, treatment and prognosis of the affection.

*A Treatise on Massage, Theoretical and Practical: Its History, Mode of Application and Effects, Indications and Contra-Indications and Results in over Fifteen Hundred Cases.* By DOUGLAS GRAHAM, M.D. Second Edition, revised and enlarged, 8vo, pp. x, 342. New York: J. H. Vail & Co. 1890.

The previous edition of this work has already been reviewed in these columns, and is doubtless familiar to many. The present edition has been thoroughly revised and enlarged. The author has collected in the historical chapters many new and curious items in regard to the use of massage, rubbing or manipulations in the old days, among others an indication of its use on Mary Stuart and Pope Clement VIII. Two new chapters, one on the use of massage in scoliosis, the other on local massage for local neurasthenia, have been added. The author's own experience is supplemented by a very extensive review of the literature of the subject, and abundant evidence is brought forward from all sources for or against the use of massage in various affections. It need hardly be stated that the author is an enthusiast in favor of massage, and that his estimates of its value are probably too great in many cases. The present work, however, gives evidence of much study and contains a very complete summary of our present knowledge of the subject. It is written, moreover, in an entertaining although somewhat controversial style, and is one of the best treatises on the subject with which we are familiar.

*Massotherapy: or Massage as a Mode of Treatment.* By WILLIAM MURRELL, M.D., F.R.C.P. Fourth edition, 12mo, pp. vi, 236, eleven illustrations. Philadelphia: P. Blakiston, Son & Co. 1890.

The previous editions of this work have from time to time been mentioned in these columns, and the merits of the book are well-known. In the edition before us more minute directions are given for the performance of certain manipulations, and some new illustrations are added.

*Operation Blank.* Prepared by W. W. KEEN, M.D., Professor of the Principles of Surgery in the Jefferson Medical College, Philadelphia. Phila.: Lea Bros. & Co.

These blanks are bound in blocks of fifty, and each block has on its back a list of instruments required in various operations. The blank is divided as follows into the details required for the preparation of (1) The patient; (2) The room and bed; (3) Dressing; (4) Medicines, etc. An operation blank of this description is of undoubted value in preparing to operate, especially where operations are carried out as at present. The preparations that a surgeon has to make are multitudinous, and any device which assists in arranging the details is of value.

*A Compend of Gynaecology.* By HENRY MORRIS, M.D. With forty-five illustrations. Philadelphia: P. Blakiston, Son & Co. 1891.

This is one of "Blakiston's Quiz Compend," and is really more elaborate than its name purports. It is a short, concise and quite complete summary of the whole field of diseases of women. Is not full enough for a text-book, but to refresh the memory with the more important leading facts of the subject, it is very well adapted. The facts are very judiciously selected, and the perspective is well preserved. The illustrations are good, and add to the value of the book.

THE BOSTON

**Medical and Surgical Journal.**

THURSDAY, MAY 21, 1891.

*A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.**SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.**All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.**All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.**Remittances should be made by money-order, draft or registered letter, payable to*DAMRELL & UPHAM,  
283 WASHINGTON STREET, BOSTON, MASS.

## ENGLISH REGISTRATION.

"THE General Abstract of Marriages, Births, and Deaths in England for 1890," and "THE Annual Summary of Births, Deaths, and Causes of Death in London and other Great Towns" have been received. These abstracts are published considerably in advance of the full report of the Registrar-General which appears later in the year.

From the general abstract we learn that there were in England in 1890, 445,376 persons married, 872,515 born, and that 564,248 died. Of the births 443,639 were males, and 428,876 were females; and of the deaths, 291,633 were males, and 272,615 were females.

These figures represent upon an estimated population of 29,407,649 a marriage-rate of 15.14 per 1,000, a birth-rate of 29.67 per 1,000, and a death-rate of 19.19 per 1,000.

(The ratios for Massachusetts in 1889 were: Marriage-rate 18.7 per 1,000, birth-rate 26.2 per 1,000, and death-rate 19.2 per 1,000.)

From the Annual Summary for London and other Great Towns we gather the following facts:

These twenty-eight "great towns" contained an estimated population of 9,716,559 persons in 1890.

The births among them represented a ratio of 30 per 1,000, and the deaths 21.3 per 1,000 as compared with an average death-rate of 20.8 for the previous eight years.

The rates for different cities varied from 16.5 in Nottingham to 30.6 in Manchester.

From certain infectious diseases the mortality in twenty-eight great towns was as follows:

There were only ten deaths from small-pox, four of which were in London. The mortality from measles was 0.63 per 1,000. From scarlet fever it was 0.31 per 1,000 as compared with 0.38 for the previous ten years. From diphtheria it was 0.24 per 1,000 as compared with 0.18 for the previous ten years. These rates do not include croup. From whooping-cough it was 0.59 per 1,000 as compared with a decen-

nial average of 0.60. From diarrhoea it was 0.77 per 1,000 as compared with a decennial average of 0.89. The infantile death-rate (children under one year) was 172 per 1,000 registered births as compared with an average of 162 for the previous ten years.

The following comments upon the great epidemic of influenza appear in the Report:

"The increased mortality from diseases of the respiratory system was remarkable. In 1889, there had been a saving of 4,376 lives under this head, when the yearly mortality was compared with the average of the previous decennium, but in 1890 this saving was transformed into a loss of 2,143 lives. . . .

"The excessive mortality from lung diseases in the first month of 1890 was due to the same cause as were the deaths ascribed to influenza. The excess in the last month of the year, on the other hand, which, though not so great as the earlier excess had been, was nevertheless sufficiently formidable, inasmuch as the mortality from lung diseases was forty-four per cent. above the average for the ten previous Decembers, was doubtless, in the main due to the usual cause of such excess, namely, prolonged cold, the mean temperature in the month having been 9.3° F. below the December average, and accompanied, moreover, by a succession of dense fogs. . . .

"The effects, then, of the epidemic influenza in January, 1890, must not be measured simply by the number of deaths ascribed to influenza. The excess of mortality from lung diseases in that month, at least, must also be included in the account; and there is much reason to suspect that a very large number of deaths under other headings should also be similarly included; inasmuch as otherwise inexplicable rises occurred under them. The mortality from phthisis suddenly shot up in the first week in January, and remained far above the average for ten weeks in succession, although the death-rate from this disease in London had been declining for years past, and was below the average in almost every week of 1890, except these first ten. A similarly sudden increase occurred in January among deaths from diseases of the organs of circulation. In short, it probably would not be far from the truth if the whole increase in mortality from all causes in the aggregate during the mild month of January were attributed to influenza; in which case that disease would have to be credited with having caused 2,258 deaths in London in the first four weeks of the year alone."

The Summary is accompanied with several very comprehensive diagrams which represent the average weekly mortality for a series of years from all causes and from certain infectious diseases; some of these cover a period of fifty years, and others shorter periods.

GLANDERS IN WORCESTER. — It is reported that several horses in Worcester have been found to be suffering from glanders, and that one man has been infected.

# THE NECESSITY FOR IMMEDIATE SURGICAL INTERVENTION IN LACERATIONS OF THE PERINEUM.

THE misfortune which has just happened to an unfortunate practitioner, who was mulcted damages to the amount of nine hundred dollars and costs by the Superior Court for neglecting a lacerated perineum, should be a lesson to every accoucheur in this country. It was shown that the laceration was complete, extending into the rectum, and had been followed by proclivencia of the uterus and other distressing accidents.

The duty of attending to all extensive lacerations of the perineum at the time when the lesions are fresh is insisted upon by the best obstetrical writers, and it is certainly the practice of the most successful obstetricians in this country to immediately put in three or more deep stitches, thus approximating and keeping in apposition the lacerated parts till union takes place. It matters little what material is used for the sutures; some use chromicized catgut, and make a deep continuous suture, and certainly catgut has in many instances proved to be sufficiently enduring; others prefer silk, others silver wire. Every physician has, or ought to have in his pocket-surgical-case ligatures and curved needles, and if a sufficiency of interrupted sutures are inserted immediately after confinement, the old-fashioned quilt suture may well be dispensed with. It will not always be necessary to give the patient ether in order to insert the stitches, though some nervous and susceptible subjects may require it. It is true that after a long and difficult confinement case, the medical attendant is generally tired out and shrinks from another operation, especially where anesthesia is required, but he must muster strength and nerve for the occasion if he would escape liability to a suit for malpractice; and if he inserts a few stitches he will save himself from the imputation of ignorance or carelessness. Modern juries have not the name of being very tender to the feelings, reputation or pockets of physicians, and it goes without saying that the most vigilant and attentive will be the least likely to be "caught napping."

There are one or two errors that should be cleared away, lest they should be subterfuges for the careless. The one is that tying the knees of the patient together will answer the same end as sutures. "Only a very credulous person," says Lusk, "really believes that he has witnessed union by first intention in extensive ruptures as the result of tying the knees together, and enjoining rest upon the side. The action of the transverse-perineal muscles tends to draw the torn surfaces apart. Moreover, the necessity of separating the knees in passing urine, and to enable the nurse to clean the genitalia, makes it impossible to keep them in contact for any lengthened period."

The other mistaken notion is that primary perineorrhaphy rarely succeeds, "that the perineum is not merely torn but is contused and mangled and that the previously oedematous and infiltrated tissues are pre-

disposed to gangrene, and consequently are in the worst possible condition for immediate union" (Charpentier). Moreover, it is said that the lochial discharge will always be an obstacle to union by first intention.

According to the experience of very many who have tried the immediate operation, and who have seldom or never failed to obtain good union; if due pains toward cleanliness and antiseptics are taken, no such unfavorable result as Charpentier points out need ever be feared. Certainly, Charpentier's American editor warmly favors the immediate repair of any laceration beyond the first degree, for the reason that thus a possible entrance site for septic matter is prevented, and also because the operation is a simple affair after delivery, and more extensive and complicated, the longer we wait. He recommends that in case of laceration to the second degree only one deep silk or wire suture should be used; if the rent be deeper, three to five will be needed. In any event, the patient should be placed on her side, a wad of absorbent cotton inserted into the vagina to catch the discharges, the wound carefully washed and trimmed of jagged shreds, and then, guided by the finger in the rectum, the suture is passed deeply around, at one-half inch from the margins. The line of suture should be dusted with iodoform, and a narrow strip of cotton laid along the perineum and the posterior vaginal wall. The after-treatment will consist in dusting with iodoform twice daily, and replacing the strip of cotton by a fresh piece till the sixth or seventh day, when the sutures may be removed.

## THE MASSACHUSETTS REPORT ON WATER-SUPPLIES.<sup>1</sup>

THE useful advice which this State Board of Health has been able to give to cities and towns is a sufficient justification of the wisdom of the law requiring of them a supervision of the water-supplies and drainage of the State. Their first report to the legislature, giving the results of their investigations under the act is packed with information of the greatest sanitary and administrative value upon the important questions of examinations, chemical and biological, of the one hundred and thirty-five water-supplies and of the eighteen river-basins in the State, including the larger streams and their tributaries; the chemical examination of waters and the interpretation of analyses; the organisms, excepting the bacteria, found in the waters of the State; a summary of water-supply statistics, with records of rainfall, flow of streams and temperatures of air and water; a classification of the drinking waters of the State; special topics relating to the quality of public water-supplies; the pollution and self-purification of streams.

The volume constitutes an important contribution to

<sup>1</sup> Examination of the State Board of Health of the Water-Supplies and Inland Waters of Massachusetts, 1887, 1890. Part I of Report on Water-Supply and Sewage, pp. 857. Wright & Potter Printing Co., State Printers. Boston, 1890.

our knowledge of the distinction between normal and polluted waters; the chemical evidence of the pollution of waters; normal chlorine; the idea of permanence, and of various degrees of susceptibility to decay, in organic matter in water; the absence of dissolved oxygen and the hindrance to self-purification of organic matter in some waters at considerable depths, at some seasons of the year; the effect of growing plants in the purification of waters; the chemical evidence of bacterial action in the character or state of the changes of organic matter; the normal differences in surface waters and ground waters; the influence of the seasons of the year on the composition of surface waters.

The results of these various examinations by the chemist, biologist, sanitarian and engineer, comprise a fund of information which must be of incalculable value to the public health administration of the State. Thus far it is shown that nearly one-half of the public water-supplies are unpolluted by sewage; that a large portion of the remainder have been so purified by filtration through ground or by organic growths, that they cannot be considered injurious to health; that in a small number there is a degree of pollution which suggests the possibility of danger or is actually dangerous.

#### MEDICAL NOTES.

THE NEW YORK MEDICAL PRACTICE BILL approved last June has been amended as follows: "This Act shall not apply to any student who duly matriculated in some legally incorporated medical college before the 5th day of June, 1890, provided that such student within three months after the enactment of this amendment shall file with the Secretary of the Board of Regents of the University of the State of New York, a certificate setting forth the fact of such matriculation, verified by the applicant, and signed by the secretary of the faculty of the college in which he matriculated."

THE AMERICAN ACADEMY OF MEDICINE. — The Sixteenth Annual Meeting of the Society was held in Washington, May 2d and 4th. The following officers were elected for the coming year: President, Dr. Phineas Conner, Cincinnati; Vice-Presidents, Dr. R. Lowry Sibbet, Carlisle, Penn.; Dr. George Jackson Fisher, Sing Sing, N. Y.; Dr. Henry M. Lyman, Chicago; Dr. Lewis S. McMurtry, Louisville, Ky.; Secretary, Dr. Charles McIntire, Easton, Penn.; Assistant Secretary, Dr. Edgar M. Green, Easton, Penn.; Treasurer, Dr. J. Cheston Morris, Philadelphia.

THE AMERICAN MEDICAL TEMPERANCE ASSOCIATION. — An association with the above name was organized in Washington during the recent meeting of the American Medical Association. The objects of the association are to advance the practice of total abstinence in and through the medical profession, and to promote investigation as to the action of alcohol in

health and disease. It aims at being a bond of union among medical abstainers scattered all over the country. It admits as members regular medical practitioners who are practical abstainers from all alcoholic liquors as beverages. Members are not required to sign any pledge, and if such for any reason cease to be total abstainers, it is expected that notice of withdrawal from the association will be sent to the secretary. The liberty of members in prescribing alcohol as a medicine is entirely uncontrolled. There is a similar association in Great Britain. The following officers were elected: President, Dr. N. S. Davis, of Chicago; First Vice-President, Dr. R. Quimby, of New Jersey; Secretary, Dr. T. B. Crothers, of Hartford; Treasurer, Dr. George W. Webster, of Chicago.

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION is to remain in Chicago. The project of the trustees, a year ago, to remove the Journal to Washington met with so much opposition that it was referred to the Association at its annual meeting this year, where it was decided by an overwhelming majority to keep it in Chicago. The Board of Trustees being unable during the session of the Association to elect an editor to fill the place of Dr. John H. Hollister, resigned; held on adjourned meeting in Chicago last week, and elected Dr. J. C. Culbertson, of Cincinnati, the present editor of the *Lancet-Clinic*.

MILWAUKEE DEATH CERTIFICATES. — The Health Office of Milwaukee have issued a new blank for death certificates, in which the "cause of death" has been divided into primary and secondary, and giving an explanation of what is meant by primary cause and secondary cause. Physicians are also obliged to fill out the personal details of the deceased, and forward the certificate to the Health Office. The blank is similar to the one in use in Boston a few years ago, which medical men were glad to see abolished. There are some good suggestions on the Milwaukee blank: "In cases of death from hæmorrhage state the place of hæmorrhage. Avoid general terms, as disease of brain, of liver, of spine, of lungs, etc., and report the general character of disease. Whenever it is possible to be specific, do not report old age, debility, paralysis of brain, heart failure or breath failure, and like terms of indefinite meaning."

PAN-AMERICAN MEDICAL CONGRESS. — As had been previously announced, the subject of an invitation to all States on the American continent to participate in a medical congress to be held in connection with the Columbian exhibition in Chicago, was brought up at the annual meeting of the American Medical Association, and referred to a committee, which is to report later in the year.

EPIDEMIOLOGY OF INFLUENZA. — The *British Medical Journal* says that in spite of considerable increase in our knowledge of the behavior of epidemic influenza gathered during the past year, much still remains very mysterious. It is, however, certain that one attack does not protect from a second, as already

many persons who suffered during the last epidemic have suffered again now. A curious point, however, is that the disease, it appears, tends to recur at long intervals, each recurrence consisting of two, or sometimes three, epidemics. We find, on referring to Dr. Symes Thompson's historical survey in his edition of his father's work on Influenza, that an epidemic occurred in 1510, and again in 1557 and 1580. A long interval then elapsed without reliable records until 1658, 1675, and 1710. A series then occurred—1732-3-7-8-43—during which the disease was scarcely absent for more than three or four consecutive years. After an interval of fifteen years came the epidemics of 1758-62-67-75-82. Twenty years then passed till the 1803 epidemic; then, after an interval of twenty-eight years, that of 1831. As in the preceding century, the "thirties" proved fertile, for 1831-33, and 1837 were all years of marked epidemic prevalence. Ten years later came the 1847 epidemic, which Dr. Peacock described so accurately; then, after an interval of forty-two years, that of 1889-90, to be followed this year by further epidemic prevalence.

**THE KOCH INSTITUTE.**—The introduction of a bill in the Prussian legislature to endow the Koch Institute last week was made the occasion of a legislative debate on the value of the remedy. There seemed to be a feeling that the government had patronized tuberculin with a little too much enthusiasm. Virchow is said to have opposed the grant, which was nevertheless voted, the sum being about \$40,000.

**SUDDEN DEATH AFTER BAPTISM.**—In a town of North Germany a girl of twenty-one died suddenly of heart failure very soon after being submerged in cold water for baptism. The case attracted a good deal of attention, the pastor was arrested, and condemned to a week's imprisonment, but appealed and was acquitted. As a consequence of this accident the Baptists of the province now warm the water before baptizing.

#### BOSTON AND NEW ENGLAND.

**RESIGNATION OF DR. FRANCIS MINOT.**—Dr. Francis Minot has resigned the Hersey Professorship of the Theory and Practice of Medicine at the Harvard Medical School.

**FOUR YEARS' COURSE AT THE HARVARD MEDICAL SCHOOL.**—The faculty of the Harvard Medical School at their last meeting voted that with the class entering in September, 1892, the regular course necessary to obtain the degree of M.D., shall be four years.

#### INFECTIOUS DISEASES IN BOSTON DURING APRIL.

A comparison between the months of April, 1891, and April, 1890, shows that this year the number of cases of diphtheria reported was 71 against 164 last year; whereas 501 cases of measles occurred this year against 31 in 1890. There was a slight increase in scarlet fever, 151 to 122. Typhoid fever remained about the same, 21 to 25.

**STREET-WATERING.**—At a public hearing on this subject before a committee of the Boston City Government, Dr. J. C. Warren called attention to the danger from the dust-laden air, not only to abutters, but to every one who uses the streets. Dr. J. H. Barnes said that streets paved with asphalt do not need watering, if they are kept clean, but the more travelled streets, paved with cobble-stones, need it.

**MEMBER OF THE MASSACHUSETTS STATE BOARD OF HEALTH.**—Morris Schaff, of Springfield, has been nominated to membership on the board in place of J. A. Appleton, whose time has expired.

**DISTRICT MEDICAL SOCIETIES.**—The following officers have been elected for the ensuing year: Hampshire: President, G. F. Thomson; Secretary, A. H. Hoadley; Treasurer, C. W. Cooper. Essex South: President, W. W. Eaton; Secretary, J. E. Simpson; Treasurer, G. Z. Goodell. Bristol South: President, S. W. Haynes; Secretary and Treasurer, A. J. Abbe. Norfolk: President, Joel Seaverus; Secretary, J. C. D. Pigeon; Treasurer, E. G. Morse. Franklin: President, W. H. Pierce; Secretary and Treasurer, F. H. Zabriskie. Barnstable: President, Samuel Pitcher; Secretary, E. E. Hawes.

#### NEW YORK.

**TRICHINIASIS.**—During the past week two fatal cases of trichiniasis, the first of this disease met with for a considerable time, have been reported. The patients were a German and his wife, residing in East 16th Street, in the heart of a swarming German tenement-house population, and they died in St. Francis Hospital. Dr. Edson, Chief of the Bureau of Infectious Diseases, has notified Dr. E. W. Martin, the chemist of the Board of Health and the head of the Meat Inspection Department, to make a careful examination of samples of raw pork and sausages from the shops in the vicinity, and search is also being made for other cases of the disease.

**THE PHELPS PAVILION** of the New York Skin and Cancer Hospital, which is situated at the country branch of the hospital, at Fordham Heights, was formally opened on May 16th, with appropriate ceremonies, although the unpleasant weather interfered considerably with the attendance of visitors. After the addresses, which were by Dr. D. B. St. John Roosa and others, a collation was served, and the new pavilion and the other buildings were thrown open for inspection. This pavilion is the gift of Mrs. Anson Phelps Stokes, and is designed for women suffering from cancer. The hospital has altogether seventeen acres of land splendidly situated on high ground overlooking the Harlem River and the city beyond.

**NEW YORK CANCER HOSPITAL.**—On the same afternoon also, a reception was held at the New York Cancer Hospital, situated on Central Park, West, at 105th and 106th Streets, to celebrate the opening of the new Astor Pavilion for male patients, and of the new Cullum Chapel belonging to the institution.

## Miscellany.

### NASAL OBSTRUCTION.

At a recent meeting of the Medical and Surgical Society of Baltimore, Dr. Jno. N. Mackenzie urged more careful attention to the nose than it receives, in combating different abnormal conditions. Respiration should be through the nose, and should be unobstructed. If it is not, the cause of the obstruction should be found and removed. Sir Morell Mackenzie thought that the so-called American catarrh is due to dust in the air; the author is of the opinion that our sudden changes of the temperature are at least as much to blame. They both act by inducing congestion of the nasal erectile tissue, and finally hypertrophy and obstruction by continued irritation.

Mouth breathing is the cause of different forms of damage to the respiratory tract; the inspired air being cold and filled with impurities. In order to fulfil their function the Eustachian tubes require nasal respiration. Obstruction in the nasal cavity will cause obstruction in them, interfering with the admission of air to the middle ear, and inducing middle ear disease. Different affections of the eye may also be traced to the same source.

### AINHUM.

Two cases of this curious disease have recently been reported, one by Surgeon H. J. McC. Todd,<sup>1</sup> occurring in a Krooman. The left toe was enlarged to twice its natural size, and was twisted on its axis so that the nail looked outwards, and was so loosely connected to the foot that it looked as if he would lose the member if it struck against anything. He had no power of moving it in association with the other toes, and its sensation was very deficient. On a level with the web of the toe was a very tight constriction, which on the inner and plantar surface had ulcerated, but on the outer side was represented by a firm band of fibrous tissue; the right little toe was surrounded by a similar tight band, which, however, had not broken down. The left toe was first affected four years ago, and the right about one year since. No cause for his disease could be found except the prevalence of this affection in that part of the West Coast from which he came. The popular remedy there is to tie a piece of string over the seat of the constriction, and to tighten this from time to time until the toe drops off, this occupying about three months. This man was of very good physique, and, excepting his troublesome toe, was in excellent health. On examining the excised toe after amputation, it was found that the constricting band had reduced the structures below it to great thinness. There was a greatly increased development of adipose tissue in the enlarged portion, giving the sensation of fluid before removal.

Mr. Gordon Messum<sup>2</sup> describes a similar case, and says that this complaint is commonly met with amongst the natives (Kaffirs) of South Africa, especially in Northern Transvaal, and is usually limited to the little toe; both feet are, however, generally attacked, though not simultaneously. The toe at its junction with the foot has the appearance of being gradually cut off by means of the continuous pressure of a ligature tied round the toe at that spot.

### THE TREATMENT OF PHTHISIS BY MEDICATED AIR UNDER PRESSURE.

GERMAIN SEE<sup>1</sup> has given his results in the treatment of phthisis by continued inhalation of air under pressure containing creasote and eucalyptol. The air was first passed through a solution of the drugs, and then raised to an increased pressure of one-half atmosphere, which pressure is gradually increased. Some patients bore the increase of pressure better than others, and for a longer time, some of them remaining from two to four or more hours in the cabinet daily. The effect upon the general health was beneficial, whilst a very marked improvement was noted in the symptoms of the disease. Cases of phthisis in early as well as advanced stages were treated with satisfactory results. In two cases of fetid bronchorrhœa of two years' duration, a complete recovery was brought about in the course of five weeks. The author claims for this method that the actual absorption of the antiseptic drug is more complete, and approaches more nearly to the point at which it is assumed that morbid organisms may be annihilated. It is harmless in itself, and gives rise to no unpleasant consequences such as may follow the continued introduction of creasote subcutaneously or by the stomach. Inhalation of creasote vapor at ordinary atmospheric pressure has long since been proved to be insufficient for the purpose of checking the progress of tubercle. Improvement of appetite, gain of weight, diminution of cough and expectoration, and subsidence of fever would appear to be the most striking of the changes brought about by the treatment.

### AN AID TO PALPATION.

CHLAPOWSKI finds that for palpation of tumors of the abdomen an excellent method is to put the patient into a well-filled bath tub. The advantages gained are several: the reflex contraction of the abdominal walls is overcome; it is very easy to change the position of the body without exertion on the part of the patient; and the pain on pressure is diminished. The author has had especially good results in determining the nature of tumors in the region of the cæcum, and in mapping out infiltration due to old appendicitis. He has also been able to determine the nature of floating kidneys, splenic tumors and different new growths, where previously the contraction of the abdominal muscles had prevented satisfactory examination.

### TRACHEAL TUGGING.

MACDONNELL, in a paper in the *Lancet* of March 7th and 14th,<sup>2</sup> called attention to a method of examination which he says is of great aid in diagnosing aneurism of the transverse arch of the aorta. It was first described by Oliver in 1878, but has never come into general use. The process is as follows: Place the patient in the erect position and direct him to close his mouth and elevate his chin to the fullest extent; then grasp the cricoid cartilage between the finger and thumb and use gentle upward pressure on it, when, if dilatation or aneurism exist, the pulsation of the aorta will be distinctly felt transmitted through the trachea to the hand. The act of examination will increase laryngeal distress should this accompany the disease.

<sup>1</sup> *Bull. de l'Acad. de Médecine*, No. 15, 1891.

<sup>2</sup> *New York Medical Journal*, May 24.

<sup>1</sup> *British Medical Journal*, February 21.

<sup>2</sup> *Lancet*, April 25.

The physical sign is known as "tracheal tugging." With a view of forming a just estimate of its value, the author has collected the histories of all the cases of thoracic aneurism recorded in the case-books of the Montreal General Hospital since 1878, omitting those in which the absence or presence of tugging was not definitely noted. The cases are twenty-three in number, and to these he has added two observed in private practice. In seventeen of the twenty-five cases tracheal tugging was noted. An autopsy was obtained in eight of the seventeen confirming the diagnosis. After a careful analysis of the twenty-five cases, the author feels warranted in making the following statements: Tracheal tugging is never present except in aneurism. When tracheal tugging is present, the aneurism is so situated as to press from above downward on the left bronchus, or upon that portion of the trachea immediately adjacent to it. Tracheal tugging may be present when many other physical signs and symptoms are absent. Tracheal tugging does not occur in aneurisms which do not involve the transverse arch. Direct pressure on the trachea does not cause tracheal tugging.

Dr. MacDonnell adds that tracheal tugging is a very early sign in the history of the case. In all the cases in which it was present it was detected on the patient's admission to the hospital.

#### DIGITALIS IN PNEUMONIA.

PETRESCO, at the last International Medical Congress, read a paper recommending enormous doses of digitalis in pneumonia. He prefers an infusion made as follows:

R Digitalis leaves . . . . .	3 l.
Water . . . . .	3 vi.
Make an infusion and add syrup of orange peel . . . . .	3 l. M.

Of this a tablespoonful is given every half-hour. He has given as much as three drachms in twenty-four hours. He has had especially good results in acute lobar pneumonia. As a rule, this heavy dosage is well borne, and he has not seen a case of poisoning. In a paper in the *Therapeutische Monatshefte* for February he reviews the subject, and gives the following conclusions:

"When given in therapeutic doses digitalis has a direct antiphlogistic action. The dose may be raised as high as from 60 to 120 grains of the leaves given as an infusion within twenty-four hours. This treatment may be continued for from two to four days if the severity of the case requires it, in some cases from 300 to 375 grains of digitalis leaves being given in four or five days without symptoms of nausea, or in fact, any toxic effect. Treated with this dose, the temperature in cases of pneumonia falls from 1° to 3° C. after a single dose, and from 5° to 6° C. after three doses, while the pulse is slowed from 40 to 60 beats in the minute after six doses. This reduction in the pulse frequency and in the temperature lasts from ten to twelve days, by which time the normal condition has been gradually obtained. When improvement takes place in the circulation and respiration, this is speedily followed by a disappearance of all local signs and symptoms."

In an elaborate table of statistics the author shows the superiority of digitalis over the other methods.

When digitalis was administered the mortality sank as low as 2.06 per cent. From an experience of a very great number of cases, both of his own and of other medical men, he maintains that the doses, as given above, are perfectly harmless.

From studies as to the value of this method of treatment the author concludes that the expectant method of treating pneumonia is not only irrational but even dangerous; that the assumption that there is a definite cycle of progress in pneumonia is not warranted; that pneumonia may be cut short by an energetic rational mode of treatment, especially if the method is inaugurated at the onset of the disease, and that, finally, the claim is supported that the treatment of pneumonia with large doses of digitalis furnishes better results than that obtainable by any other mode of procedure.

#### THE COCAINE HABIT.

FALK,<sup>2</sup> in a paper on this subject, draws a clinical picture of the victims of this habit, which has much in common with the older habits of opium and alcohol. Like them the moral impairment is as characteristic as the cachexia and physical symptoms. Not infrequently victims of opium have endeavored to break up the habit by cocaine, and have thus added a second habit to the first. In these cases, and where cocaine alone is used, the patients appear marasmatic. The skin is of a pale yellowish, almost cadaveric tint and withered feel; the extremities are cool and covered with cold sweat. The eyes are deeply sunken, glistening, and surrounded by a dark ring; the pupils widely dilated. Appetite is lost; digestion disturbed. Salivation with dryness of throat may be complained of, and further, partial sensory disturbances or total analgesia. From the paralyzing action of cocaine upon the blood-vessels, patients complain of palpitation and breathlessness, troublesome sweating and noises in the ears, and also syncope attacks and dyspnea. The pulse is more frequent and easily compressible. They suffer from a want which must be satisfied; they become nervous, trembling, and fall into a wretched condition of neurasthenia. Speech is disconnected and can scarcely be understood; impotence and incontinence of urine may appear. Sleeplessness sets in early. One of the most characteristic effects of this habit is the occurrence of muscular twitching, tonic and clonic convulsions, and finally, epileptic attacks in which the patient may die. The mental symptoms may take the form of hallucinations, usually of general sensation, but not infrequently of sight as well. General mental weakness may set in rather early, to be observed in a loss of memory and unusual prolixity in conversation and correspondence. When the drug is withdrawn, besides the vaso-motor symptoms there may be seen depression, impairment of will-power, weeping, etc. The chronic form does not protect from acute intoxication.

#### CONVENIENT URINE TESTS.

To test for albumin Raabe uses trichloroacetic acid in the following manner.<sup>2</sup> About one cubic centimetre of urine, previously filtered, is poured into a narrow test tube, and a small crystal of trichloroacetic acid is

<sup>1</sup> *Therapeutische Monatshefte*, No. 12, 1891.

<sup>2</sup> *Morck's Bulletin*, April, 1891.

dropped into it; it is then set aside for a while, without shaking. The acid soon dissolves in the bottom of the test tube, and at the plane of contact of the two layers of fluid a distinctly visible and sharply defined turbid zone forms, if albumin be present. Even the slightest quantity of albumin can be detected with certainty and promptness, because the contrast between the turbid zone and the supernatant clear fluid is very distinct. According to this author, trichloroacetic acid produces no precipitation in normal urine. Only when the latter abounds in urates, a slight haze develops after some lapse of time;—this can be avoided, however, by gently warming the urine, or by diluting it with three times its volume of distilled water. He ascertained, by comparative tests, that trichloroacetic acid is decidedly more sensitive, as a test for albumin, than either nitric or metaphosphoric acid.

According to Roch<sup>2</sup> sulpho-salicylic acid is a very sensitive and reliable reagent for albumin. It is a product of the action of sulphuric anhydride on salicylic acid. By its means, the presence of egg-albumin can be proved with certainty in a solution of one part of the latter in 20,000 parts of water. To test urine for albumin, all that is necessary is to add a few crystals of the readily soluble sulpho-salicylic acid to a few cubic centimetres of clear urine and shake. The appearance of turbidity indicates, with certainty, the presence of albumin; for all the other constituents of urine—such as peptone, glucose, urea, uric acid, etc., remain in solution; the albumin alone being precipitated by this reagent.

Certain substances which may be present in urine, such as arsenic, salicylic acid, etc., may interfere with the test for sugar by either the fermentation method or with Fehling's solution. In order to eliminate this source of error Bishop<sup>3</sup> advises treating the urine as follows: The urine is first shaken with animal charcoal. As soon as the fluid appears colorless, add baryta water, boil, allow to cool, and filter. To the filtrate add cautiously a weak solution of cupric sulphate in moderate excess, allow to stand for one hour in a covered vessel, decant and filter. To the clear solution add H<sub>2</sub>S water in excess, or better, transmit H<sub>2</sub>S gas through the solution. Then filter, apply a gentle heat to expel the H<sub>2</sub>S which may be present and again filter. The solution is now practically free from everything which would interfere with the determination of sugar, and the operation may be finished by either of the usual methods.

Nothnagel communicated at a recent meeting of the Vienna Medical Association, a paper received from Dr. Becker, of Cairo, on a simplified test for sugar, which depends upon the fact that the paper used for the manufacture of visiting cards contains a large quantity of potash to make it heavier and fuller. When this paper is brushed over with a concentrated solution of sulphate of copper and then dried, the salt is crystallized on the surface. If the urine containing sugar is then added by means of a bit of wood and allowed to dry by the action of the air, or by holding it over an Argand burner (without browning the sulphate of copper), the latter is liquefied by the water contained in the small crystals, and the alkaline paper immediately produces the sugar-browning reaction. The more sugar the urine contains the darker the color produced. The author considers the test highly sensitive.

<sup>2</sup> Merck's Bulletin, April, 1891.

## PRESCRIPTIONS.

**SUBCUTANEOUS ADMINISTRATION OF IRON.**—Magagn<sup>1</sup> recommends this method of giving iron salts in severe cases of chlorosis and in cases where the digestion is disturbed by iron preparations. Three grains is the common dose. For injection he uses the following solutions:

R Ferri pyrophosphatis . . . . .	1.	i.
Aque destil. et coct. . . . .	5.	v. M.
R Ferri citratis . . . . .	1ss.	v.
Aque destil. et coct. . . . .	5.	v. M.
R Ferri pyrophosphatis . . . . .	3.	i.
Aque destil. et coct. . . . .	5.	v. M.

Of these solutions from ten to twenty minims should be used for each injection. These should be injected under the skin, preferably of the buttocks, and not into the muscle.

Deaths reported 3,155; under five years of age 1,141; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fevers) 473, acute lung diseases 548, consumption 365, typhoid fever 150, diphtheria and croup 103, diarrhoeal diseases 62, scarlet fever 53, measles 12, whooping-cough 27, cerebro-spinal meningitis 19, erysipelas 14, malarial fever 3.

From scarlet fever New York 23, Chicago 13, Brooklyn 12, Philadelphia 4, Boston 3, Lowell, Lynn, Springfield and Chelsea 1 each. From measles New York 21, Chicago 8, Brooklyn 5, Washington and Lowell 2 each, Philadelphia, Boston, Worcester and Fitchburg 1 each. From whooping-cough New York 3, Chicago 8, Philadelphia 6, Brooklyn, Boston, Washington and Nashville 1 each. From cerebro-spinal meningitis Chicago 7, New York 3, Brooklyn, Washington and Worcester 2 each, Philadelphia, Nashville and Gloucester 1 each. From erysipelas New York 5, Cincinnati 3, Chicago and Brooklyn 2 each, Boston and Worcester 1 each. From malarial fever New York 3.

In the twenty-eight greater towns of England and Wales with an estimated population of 10,010,426, for the week ending April 25th, the death-rate was 24.3. Deaths reported 1,661; acute diseases of the respiratory organs (London) 471, whooping-cough 151, measles 122, diarrhoea 51, scarlet fever 36, fever 35, diphtheria 33.

The death-rates ranged from 11.6 in Brighton to 57.8 in Sheffield, Birmingham 24.0, Bradford 25.6, Hull 36.5, Leeds 27.9, Leicester 22.1, Liverpool 26.4, London 21.0, Manchester 29.8, Norwich 24.9, Nottingham 19.6, Portsmouth 28.1, Sunderland 22.9.

In Edinburgh 18.0, Glasgow 27.3, Dublin 32.0.

In the twenty-eight greater towns of England and Wales with an estimated population of 10,010,426, for the week ending May 2d, the death-rate was 26.8. Deaths reported 5,153; acute diseases of the respiratory organs (London) 588, whooping-cough 188, measles 127, diarrhoea 53, diphtheria 57, fever 31, scarlet fever 26.

The death-rates ranged from 15.0 in Birkenhead to 70.5 in Sheffield, Blackburn 38.5, Bradford 32.0, Hull 29.2, Leeds 35.1, Leicester 22.4, Liverpool 27.2, London 23.8, Manchester 35.1, Newcastle-on-Tyne 31.3, Nottingham 21.1, Sunderland 22.2.

In Edinburgh 16.5, Glasgow 27.8, Dublin 34.4.

### METEOROLOGICAL RECORD,

For the week ending May 9, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Date.	Baro- meter	Thermom- eter.	Relative humidity.	Direction of wind.	Velocity of wind.	Wet'th'r.	Rainfall in inches.

ening; N. snow. \* Indicates trace of rainfall. † Mean for week.

### OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MAY 9, 1891, TO MAY 15, 1891.

Lieutenant-Colonel JAMES C. McKEE, surgeon, having been found incapacitated for active service by an Army Retiring Board, is, by direction of the Acting Secretary of War, granted leave of absence, until further orders, on account of disability. S. O. 106, Par. 11, A. G. O., Washington, D. C., May 9, 1891.

By direction of the Acting Secretary of War, the extension of ordinary leave of absence granted Captain HENRY P. BIRMINGHAM, assistant surgeon, in Special Orders 31, Adjutant-General's Office, April 10, 1891, from this office, is changed to leave of absence on account of sickness, to date from May 1, 1891. S. O. 108, Par. 11, A. G. O., May 12, 1891.

By direction of the Acting Secretary of War, Lieutenant-Colonel WILLIAM BACHE, surgeon, is relieved from duty as a member of the Army Medical Examining Board, New York City, and will return to his proper station, Omaha, Neb., and resume his duties as medical director, Department of the Platte. S. O. 108, Par. 5, A. G. O., May 12, 1891.

### OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MAY 16, 1891.

W. H. REED, passed assistant surgeon, detached from "Saratoga," and prepare for sea.

S. W. ATLEE, passed assistant surgeon, detached from Navy Yard, New England, and to "Saratoga."

C. D. W. BROWNELL, assistant surgeon, ordered to Navy Yard, New England, Pa.

L. H. STEVENS, surgeon, detached from Naval Examining Board, and prepare for sea.

R. S. MASON, surgeon, ordered as member of Naval Examining Board.

L. W. CURTIS, passed assistant surgeon, detached from Naval Academy, and to the Practice-ship "Constellation."

PHILIP LEACH, passed assistant surgeon, orders to U. S. Practice-ship "Constellation" revoked.

### OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE, FOR THE WEEK ENDING MAY 9, 1891.

AUSTIN, H. W., surgeon. Detailed as chairman of Board for physical examination of candidates for appointment. Revenue-Marine Service. May 9, 1891.

CARRINGTON, P. M., passed assistant surgeon. Granted leave of absence for twenty-three days. May 5, 1891.

BRATTON, W. D., passed assistant surgeon. When relieved at Portland, Oregon, to proceed to Chicago for duty. May 9, 1891.

MAGRUDER, G. M., passed assistant surgeon. Detailed as recorder of Board for physical examination of candidates for appointment, Revenue-Marine Service. May 9, 1891.

CONDUCT, A. W., assistant surgeon. Relieved from duty at Chicago, Ill., ordered to Portland, Oregon. May 9, 1891.

GEDDINGS, H. D., assistant surgeon. To proceed to New York on special duty. May 9, 1891.

BROWN, B. W., assistant surgeon. To report to commanding officer Revenue Steamer "Rush" on the 14th instant. May 7, 1891.

### SOCIETY NOTICE.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.—A regular meeting of the Society will be held on Monday, May 25, 1891, at the Medical Library, 19 Boylston Place, at 8 o'clock P. M.

Dr. G. L. Walton will read a paper written in conjunction with Dr. C. F. Carter on "The Etiology of Epilepsy with Special Reference to Infantile Convulsions"; Dr. F. C. Shattuck, "A Case of Graves's Disease with Acute Pericarditis, Paracentesis of the Pericardium; Recovery."

G. G. SEARS, M.D., Secretary.

### VRICHOW TESTIMONIAL FUND.

The Boston members of the American Committee take pleasure in acknowledging the following contributions:

Amount previously acknowledged	\$402.00
Through James T. Whittaker, Cincinnati	105.00
Henry I. Bowditch, Boston	5.00
William D. Baker, Boston	5.00
William W. Gannett, Boston	5.00
Frederick Tuckerman, Amherst	5.00
George S. Osborne, Peabody	3.00
W. Sturgis Bigelow, Boston	25.00
Algernon Coolidge, Boston	10.00
Henry H. A. Beach, Boston	10.00
Clarence J. Blake, Boston	10.00
J. Orne Green, Boston	10.00
Otis K. Newell, Boston	5.00
Morton Prince, Boston	5.00
James J. Putnam, Boston	5.00

### ERRATUM.

Dr. R. J. Dunglison, of Philadelphia, is still treasurer of the American Medical Association, and not Dr. W. E. Taylor, of California, as stated in the issue of the JOURNAL May 7th, page 466.

### DEATHS.

ALFRED BOSMER, M.D., M.M.S.S., died in Watertown, Mass., May 11th, aged fifty-eight. Dr. Bosmer was born in Newton, graduated from Harvard College in the class of 1853, and from the Medical School in 1856. He was President of the Massachusetts Medical Society in 1882 and 1883, the first President of the Massachusetts Medical-Legal Society, and held many other positions of honor and trust.

ARTHUR H. GRIMSHAW, M.D., of Wilmington, Del., died, May 14th, aged sixty-six.

GEORGE A. KING, M.D., of Lancaster, Pa., died, May 16th, aged forty-eight.

JOHN WITTEK, M.D., of Putnam, Conn., died, May 16th, aged sixty.

GEORGE N. BOWELL, M.D., of Buffalo, N. Y., died, May 15th, aged seventy-two.

PROF. ALEXANDRE EDMOND BEQUEREL died in Paris, May 12th, aged seventy-one.

Dr. JULIUS JENSEN, the author of several works on mental disease, died in Berlin, April 21st, aged forty-nine.

## Original Articles.

A CASE OF COMPOUND DISLOCATION OF THE HIP.<sup>1</sup>

BY DAVID W. CHEEVER, M.D.

On the 28th of last November, T. H., a strong and healthy laborer, aged fifty, while assisting to remove a case weighing about six hundred pounds, from a "caravan," was knocked down by the case, which slipped on the tail-board of the wagon, and falling on him pinned him to the sidewalk. He was carried at once to the City Hospital, where it was found that he had a compound dislocation of the right hip. He could not tell exactly how he lay upon the sidewalk, or how the case held him.

In the right groin there was a small lacerated wound just large enough to allow the protrusion of the head of the femur, which clean and unbroken, with half the ligamentum teres attached, lay upon the pubes just below the anterior superior spine of the ilium, exposed to the air. The limb was shortened, semi-flexed, everted and abducted. There was considerable venous hæmorrhage. Pulsation was absent in the arteries of the foot, but returned when the limb was raised and inverted. There was no other apparent injury.

The patient was etherized, and the wound was enlarged so as to admit the finger. The socket was apparently uninjured. The head of the femur was excised, and the shaft of the bone dropped back readily into place. After this the limb was without difficulty brought back into its proper position. A counter opening was made in the outer side of the thigh

through the fascia lata; and two large drainage-tubes inserted, one in each wound. An antiseptic dressing was then applied.

The patient rallied well from the operation, and on the next day (November 29th) appeared to be doing fairly well.

The dressing was changed on November 30th, on account of saturation from blood. The patient's condition, on the whole, appeared to be fairly satisfactory. Towards night a change for the worse with feeble pulse and delirium; and early on the next morning (the third day after the operation) he died.

Dr. W. W. Gaunet performed the autopsy twelve hours later. The pelvic bones were intact. There had apparently been no injury to the vessels or nerves in the vicinity of the hip-joint. The cut end of the neck of the femur showed hæmorrhagic infiltration of the marrow. There were several transverse lacerations of the posterior wall of the aorta; and the tissues behind the peritoneum showed extensive extravasation of blood. The body of the third lumbar vertebra was separated from its upper cartilage opposite the cauda equina. The lungs were engorged;

<sup>1</sup> Reported at the Meeting of the Surgical Section of the Suffolk District Medical Society, March 4, 1891.

Sketched from a Photograph taken before Excision.

and a microscopic examination showed the presence of multiple fat emboli.

The extreme infrequency of this injury, and the fact that no precedents have established a rule of treatment, render it worthy of record and comment. All compound dislocations are rare, when compared with simple dislocations. Norris's table makes them two per cent. of all dislocations; Hamilton, four per cent.; Alison, about six per cent. It is probable then that about ninety-five simple dislocations occur to five compound ones.

Simple dislocation of the hip is not frequent, in comparison with the shoulder, elbow, and ankle. Compound dislocation of the hip (meaning without fracture and without crushing of the soft parts), is excessively rare. Malgaigne says it probably never occurred. Stimson, however, has collected six cases; and we can add two more, making eight. Of these, three were reduced; two were excised; one was not reduced; in one it is not stated; one died, almost immediately.

**CASE I.** In the practice of Dr. William Ingalls, of Boston, Mass., reported by Dr. William J. Walker to Sir Astley Cooper, and published in his works (p. 116), the head of the femur was forced through the groin, reduction was effected by manipulation; the patient died of extensive suppuration in three weeks.

**CASE II.** Report of the fourteenth Prussian army corps (1878). Head of femur forced through the groin; rupture of the femoral vein; death in twenty-four hours.

**CASE III.** Macouchy (Dublin). Head, neck and great trochanter of femur forced through the integuments over the sciatic notch; excision; death in two days.

**CASE IV.** Moxon. Dislocation on the dorsum; head lying bare in a rent through the gluteal muscles; speedy death.

**CASE V.** Taylor. Head of femur in the obturator foramen, and a laceration through the perineum, by which head of bone could be felt; reduction; abscess after nine weeks; recovered; and in eight months rode horseback.

**CASE VI.** Woodward (Worcester). Head, neck and great trochanter of femur lay out across the scrotum, emerging from a lacerated wound; death in five hours; after death, reduction could not be made.

**CASE VII.** Dr. John W. Perkins (1890). Head of femur thrust out on pubes, at middle of Poupart's ligament; reduced and drained; recovered; walked in three months.

**CASE VIII.** Cheever. Head of femur forced out on pubes (subspinous), clean and unbroken; small opening through skin; excised; death in two days; severe internal injuries.

Of these eight cases four were pubic, two obturator, one dorsal, one ischiatic. Four were due to moving vehicle, or train; two were due to falls; two were due to weights falling on the person. Five were of seventeen years and younger (fourteen, twelve and eight years); three were adults; two recovered (aged eight and seventeen years); six died (three youths and three adults). There are two recoveries out of eight cases, a mortality of seventy-five per cent.<sup>2</sup>

A perusal of the foregoing at which, because of none was published, I have collected the successful case of Dr. Langmaid, and the others, I have included that among those which had been reported, but of the case, he given at length in the following.

As to treatment, it is quite without settled rule, as the opinions of the following surgeons show:

Hippocrates advised the non-reduction of all compound dislocations. He says they die if reduced, and often live if not reduced. Both he and Celsus mention excision. Agnew would excise. Gross would reduce. Holmes reduced and hopes for ankylosis. Erichsen excises or amputates. Bryant is not clear. Hamilton excises, and says the future false joint is more useful than adhesions. Ashurst excises or amputates. Stimson would excise. Five excise; two reduce; one is not decided.

Such a rare accident, presenting itself as an emergency, requires immediate decision, without distinct precedent or rule. For myself, I was governed by the conservative impulses of general surgery, to excise, deeming the tension of the parts, the laceration of fascia and capsule thus best relieved, and also thus securing a drainage impossible after reduction.

Whether antiseptic dressings could avert inflammation, tetanus or suppuration, after the reduction of the head of the femur into its very deeply situated socket and torn capsule, seems to me problematical.

#### RECURRENT APPENDICITIS WITH ADHESIVE BANDS ABOUT THE HEAD OF THE COLON: OPERATION FOLLOWED BY CURE.

BY HENRY O. MARCY, M.D., BOSTON.

THE interesting paper by Dr. Charles B. Porter, published in a late number of the JOURNAL (April 2, 1891), upon operative measures for the cure of recurring appendicitis during a remission of the acute symptoms, induces me to report the following case, as an interesting contribution upon this subject. Moreover, it is the first case, so far as I have been able to learn, where operative measures were deliberately undertaken, during a remission of the symptoms, for the cure of this disease; and this conclusion was arrived at quite as much by Dr. Nelson's own deliberate opinion as from any advice I was able to give him. The following notes are condensed from a report with which Dr. Nelson has recently favored me.

Dr. Samuel N. Nelson, aged twenty-nine years, when a post-graduate student in Vienna, in March, 1885, during an operation upon the cadaver, was accidentally subjected to a severe strain. He felt something "give away" in the right iliac region. This was followed by severe pain. A few hours later he had a marked chill with an elevation of temperature. He was considered dangerously ill and was under medical care for a month, with a localized pain and swelling in the right side, diagnosed as perityphlitis. He was unable to actively resume his studies until June.

The following autumn he returned to America in good health. In March, 1886, occurred the first of a series of relapses, of which he had eight during the succeeding eight months. These relapses came on at intervals from three to six weeks each, and commenced under varying conditions of activity, some beginning in the night when asleep. The attacks, however, were very similar, being short, sharp, and very severe. The pain was the first symptom; a chill soon occurred, followed by a temperature rarely exceeding 102°. These attacks generally lasted only three or four days, when the acute symptoms subsided, and he was left in a very

weak and exhausted condition. Having suffered from three such attacks, he concluded that surgery alone could give him relief, and to this end he consulted several prominent surgeons in New York City, being at the time associated in the work at the Carnegie Laboratory; but operative measures were not advised.

A long sea-voyage was suggested as of probable advantage. Acting in accordance with this advice, he made the trip to the Azores; but, during the three months he was on board ship, he suffered severely from two attacks not unlike those previously experienced, and he returned to Boston decidedly less well than at the time of his sailing.

Dr. Nelson was under my personal observation during the last attack, which commenced with a severe chill, followed by a marked rise of temperature. There was a distinct tumefaction in the right iliac quarter, which was very tender upon pressure. The pain was so intense that it required one-fourth grain doses of morphia, administered hypodermically about every three or four hours, in order to keep the patient in any degree comfortable. The acute symptoms promptly subsided, and in three or four days he was able to sit up for a little while at a time. The swelling and tenderness were nearly gone at the end of a week. It was then determined that operative measures were imperative; and two weeks later, November 9, 1886, I operated upon him at my private hospital, assisted by the late Dr. Holt, Dr. Chapin of New York, Dr. A. P. Clarke and others.

An oblique incision was made through the abdominal wall, three inches in length, directly over the seat of the former swelling. The tissues of the abdominal wall were unchanged, and the peritoneum was healthy. The appendix was much shorter and larger than usual, but free from adhesions and empty. Slight bands of adhesions radiated in various directions from the head of the cæcum. I examined very carefully the small intestine for a considerable distance above the cæcum, also the large intestine, but both appeared to be normal. I then divided freely the bands about the cæcum, but it was the opinion of all present that the condition of the appendix did not warrant its removal, although it was undoubtedly in a degree abnormal. The wound was closed in lines of buried animal sutures, without drainage, and hermetically sealed with collodion.

The patient had developed an inguinal hernia upon the left side, which was but imperfectly retained by a truss. This I operated upon for radical cure after my usual method. Both wounds healed without suppuration, or pronounced suffering; and convalescence ensued without any noteworthy symptoms. He was discharged from the hospital the twelfth day after the operations, being conveyed to Boston in a carriage without suffering or harm.

Dr. Nelson closes the notes of his case, which he sent me within a few days, as follows: "I have not had my attention called to my abdomen by reason of pain or other symptom since recovery from the operation, and at this date I am as well as ever. In the summer of 1888, after a long period of very hard work, a right inguinal hernia rapidly developed, which despite my care soon became scrotal and could not be retained by a truss. In November, 1888, Dr. Marcy operated upon me for cure after his usual method. I have had no discomfort at the site of the hernia since either operation, and have never worn a truss."

It was the opinion of each of the surgeons present at

the operation, as well as my own, that it was exceedingly doubtful if the bands of adhesion were sufficient to have served as cause for the many severe attacks of local pain and swelling which the patient had suffered; but the resulting history of prompt and complete cure which has now remained permanent for nearly four and one-half years, indicates that in some way the adhesive bands resulting from the primary attack so interfered with the physiological functions of this circumscribed portion of the bowel as to induce the severe and oft-repeated inflammatory attacks.

I have since operated eight times for the cure of appendicitis in the acute stage, fortunately followed by recovery, save in a single instance, but during the entire period I have met with but the one case where the attacks had been recurrent.

## THE TREATMENT OF ACUTE URETHRITIS.<sup>1</sup>

BY GARDNER W. ALLEN, M.D.,  
Surgeon in the Genito-Urinary Department, Boston Dispensary.

I HAVE no new contribution to genito-urinary therapeutics to offer, but merely wish to make a few general observations on the treatment of acute urethritis in the male, based on my own experience.

The internal treatment is of some importance. The value of copaiba, I think, is apt to be underestimated, and, because it is disagreeable to take, some physicians discard it from their formulary. Many persons take it well, and it undoubtedly has a marked influence on the disease in a large proportion of cases. Where internal treatment is indicated, copaiba should be considered, but, of course, must be stopped when found to produce gastric or intestinal disturbance, or a cutaneous eruption. Sandalwood oil is perhaps even more efficient and is less nauseating. It is expensive, however, and most preparations of it are unreliable. Its action on the kidneys should be looked out for. My experience with salol is small and somewhat disappointing, as far as it goes.

For diuretics, acetate of potassium and liquor potassæ are perhaps as good as any. The latter combined with compound tincture of cardamom makes an agreeable preparation, but where there is severe pain on micturition, it works better if given with hyoscyamus.

Local treatment, however, is the most effectual, and although many advise the postponement of injections until the third week or later, it seems to me that the sooner we begin with them the better. If we are to use simple astringent injections it may be well to wait until all acute symptoms have subsided, but I think the time has come when we should consider the question whether it is not better to eliminate simple astringents from the routine treatment of gonorrhœa. They are doubtless useful in certain cases and should not be wholly neglected, but it seems to me that we now have more reliable agents, namely, antiseptics, which should always be used when practicable, beginning the treatment as early as possible. In cases of extremely intense inflammation or of phimosi with long oedematous prepuce we must, of course, defer the use of injections until a more favorable opportunity presents itself.

For injecting the urethra it would seem hardly

<sup>1</sup> Read at Meeting of the Surgical Section of the Suffolk District Medical Society, March 4, 1891.

necessary, now, to speak of the importance of using a large syringe, holding about half an ounce of fluid and having a blunt point, yet the small, sharp-pointed syringes still seem to be the favorites with most patients and many physicians. It will be found of advantage to carefully instruct patients in the use of the syringe.

Among the substances supposed to have antiseptic properties, that I have used for injections are hydnaphthol, sulphate of thallin, peroxide of hydrogen and pyroctanin, which have been on the whole rather disappointing, seeming to have few, if any, advantages over old-fashioned remedies. Permanganate of potassium and nitrate of silver make useful injections. The former is comparatively unirritating, but the latter should be largely diluted in the acute stage, a solution not stronger than from 1-4000 to 1-2000 being used. Corrosive sublimate, according to my experience, is more reliable. As an injection, in solutions of 1-8000 or 1-10000, or even weaker when irritating, it may, I believe, generally be depended upon, if not to limit the duration of the disease, at least to reduce the discharge to a thin, milky oozing from the meatus, devoid of the most disagreeable and painful symptoms.

The best results in the use of corrosive sublimate, however, are to be obtained from irrigating the urethra with a hot solution of this substance. The strength of the solution should be from 1-40000 to 1-10000. The latter is too irritating for most cases, but many patients bear 1-20000 very well, and 1-30000 is strong enough to be effective. The irrigation may be carried out by means of a fountain syringe, syphon or any other more convenient arrangement, and the solution introduced into the urethra through a soft catheter or other irrigator passed down to the bulbous portion, or through a blunt nozzle, with either a single or double current, held at the meatus. I have generally used and preferred a simple, blunt-pointed glass nozzle. Adjusting it so that the lips of the meatus fit snugly about the tip the current is turned on. As soon as the urethra seems to be fully distended, the nozzle is very slightly removed, allowing the fluid to escape, and immediately replaced. By alternately filling and partially emptying the urethra, it is thoroughly washed out, and by distending it with the fluid all the folds of the mucous membrane are laid open. I have not found this operation painful when carefully and cautiously done, sudden and violent distension of the canal being avoided. Many surgeons, however, prefer retrojection through a catheter; this is probably quite as effective, and, if the passage of the catheter is not painful, it is open to no objection. The danger in carrying gonococci into the deep urethra, even beyond the sphincter, either on the end of the catheter in retrojection, or by the force of the current in simple irrigation is probably slight, for any microorganisms would be rapidly destroyed by the solution. The chief objection to corrosive sublimate is that it is irritating. Micturition is apt to be painful during treatment. The meatus sometimes becomes very sensitive, requiring the use of cocaine in order to continue the irrigation.

To obtain the best results irrigation should be repeated two or three times a day, but this is generally impracticable. It should at any rate be done as often as possible while there is hope of aborting the disease. During the intervals and after the irrigation has been discontinued, ordinary injections of corrosive sublimate

in somewhat stronger solution, say 1-8000 or 1-10000 may be used by the patient. Or, what is still better, he may use an instrument called the universal injector, which is described by Prof. Keyes in his book. It is a hollow rubber ball, holding an ounce and a half, with a blunt nozzle on one side. It makes a good substitute for the irrigation apparatus.

Notwithstanding all that can be said, however, in favor of this treatment, we cannot, I think, feel at all confident of really cutting short the disease unless we see the case very early, that is, within twenty-four hours or perhaps within twelve hours of the very first symptom noticed by the patient. In a few cases I have succeeded in obtaining very satisfactory results. Unfortunately none of them were first attacks, but each had a purulent discharge coming on after a regular period of incubation of from three to five days. In the cases in which the discharge was examined it was found to contain gonococci. The disease was apparently aborted in these cases within a week, and did not recur.

Of course, a few isolated cases like the above do not prove much, but the results were satisfactory to the patients and to me, and I think indicate in a general way, that the antiseptic treatment is the best. For every such quick result as this there will be a number that, as I said before, if not aborted, will at least be so modified that the disease will run its course in a mild, subacute form, causing comparatively little inconvenience to the patient, and less liable to be associated with the painful and sometimes serious complications that often accompany the disease.

#### CONSERVATIVE SURGERY APPLIED TO A CASE OF GUN-SHOT WOUNDS WHERE FOUR LARGE PISTOL BALLS ENTERED THE BODY AND ONLY ONE BALL WAS REMOVED.<sup>1</sup>

BY SAMUEL N. NELSON, M.D.  
*Surgeon to the Soldiers' Home in Massachusetts.*

On Friday, May 16, 1890, at 1.30 p. m., O. M. W., aged fifty-seven years, was assisting painters who were at work upon his house. One painter was engaged on a staging about eighteen feet from the ground, and Mr. W. was on a long ladder which reached from the ground to the house. He was on a level with the staging and about five feet from the painter, who, without provocation, drew a seven-shot, self-cocking revolver of the "British Bulldog" pattern, carrying a ball 32-100 of an inch in diameter, and began firing at Mr. W. The first ball fired broke his right shoulder causing him to loosen his grasp on the ladder and in consequence he nearly fell, but succeeded in saving himself with his left hand. While attempting to step down, a second ball was fired, which entered the right forearm. When he had stepped down two rounds more a third shot was fired, the ball of which entered his back and then he lost his grasp on the ladder and fell to the ground, about twelve feet. While lying on the ground a fourth shot was fired and the ball entered his hip. The ball of the fifth shot did not hit Mr. W., and a sixth cartridge missed fire. Mr. W. got upon his hands and knees and crawled around the corner of the building out of sight of his assailant. He then arose, walked about twenty-five

<sup>1</sup> Read (and patient exhibited) at the meeting of the Surgical Section of the Suffolk District Medical Society, March 4, 1891.

feet to the rear door of his house, and fell to the ground. He was helped into the house where I found him soon afterwards, and, assisted by Dr. Willis G. Bond, I gave him ether and explored with a fine uterine probe, which had been thoroughly sterilized, in an attempt to locate the bullets and ascertain if any pieces of clothing or other foreign material had entered the wounds.

The first ball entered the right shoulder, passed through the deltoid muscle, shattered the surgical neck of the humerus and then took a downward course, curving spirally around the shaft of the bone. It was traced to a point four and one-half inches below the point of entrance and then its tortuous course was no longer followed.

The point of entrance of the third ball was nearly over the lower angle of the right scapula four and one-half inches from the median line. The course of the ball was directly backwards. It passed just under the skin and was traced as far as the spinal column, a distance of four inches from the point of entrance. Although its exact position was not located, there was no evidence that it had entered the thoracic cavity, and it was believed that it was imbedded somewhere in the vertebrae or muscles and in a safe position.

Search for the fourth ball showed the point of entrance to be on a level with the crest of the ilium and three inches to the right of the median line. This ball was traced downwards and backwards for five inches, and it was believed to be imbedded in the glutei muscles.

The second ball entered the right forearm on its outer and posterior aspect about three inches below the elbow-joint and it passed through the whole thickness of the forearm, boring a hole through the ulnar and somewhat splintering it. The ball was found underneath the skin on the inner and anterior aspect of the forearm, and was easily removed. This was the only one of the four balls at which any attempt at removal was made, it being believed that the others were in safe places and that they ought to remain where they were unless unfavorable symptoms set in.

Each wound was carefully washed with sublimate solution, and dressed with iodoform. The right arm was fixed to the side with the elbow at right angles by means of adhesive plaster and with the same material a shoulder cap was made, which sufficed to hold the shattered humerus in position and to restrain all movement of the shoulder-joint.

He rallied quickly from the ether and made a speedy and remarkable recovery. The wounds were dressed every two or three days with antiseptic precautions and they healed without any suppuration. There was no paralysis of any description and at all times there was control of the splinters. For the first few days the urine was drawn with a catheter. Fourteen days after the injury the patient was walking about the house, and thirty-two days afterward the confining plasters were all removed and a simple sling substituted; with which the patient rode two miles to a police court to confront his assailant.

Friday, May 16, 1890. Wounded at 1.30 p. m.; 9 p. m., temperature 98° F., pulse 72, respiration 21.

Saturday, May 17th. 8.30 A. M., temperature 98°, pulse 88, respiration 22; 1.30 p. m., temperature 100.1°, pulse 88, respiration 24; 6 p. m., temperature 101.4°, pulse 100, respiration 24; 9 p. m., temperature 100.5°, pulse 100, respiration 21.

Sunday, May 18th. 10.30 A. M., temperature 99.6°, pulse 100, respiration 20; 2.45 p. m., temperature 99.5°, pulse 104, respiration 20; 9 p. m., temperature 100, pulse 100, respiration 22.

Monday, May 19th. 2.50 A. M., temperature 98.4°, pulse 96; 8.15 A. M., temperature 98.2°, pulse 96, respiration 14; 3 p. m., temperature 99°, pulse 92, respiration 17; 9 p. m., temperature 100°, pulse 100, respiration 22.

Tuesday, May 20th. 8 A. M., temperature 98.5°, pulse 84, respiration 14; 8 p. m., temperature 100°, pulse 96, respiration 21.

Wednesday May 21st. 7.30 A. M., temperature 98.5°, pulse 80, respiration 15.

The motion of the shoulder was gradually restored until now he can put his hand to the top or even back of his head; and can put it behind his back as high as the waist line; and in reaching up he can reach within three and one-half inches as high with the hand of his injured side as with the other. That the man did not receive mortal injury from some one of the numerous wounds from a pistol fired at short range is remarkable and is due primarily to the fortunate points of injury; but the good results attained in this case are believed to be due to two main factors. First, that the patient had a good constitution, for he had been a man of good habits; and second, to the conservative attitude taken: for if the probing had been prolonged or repeated, or if the long deep tracks of the bullets had been opened, in an attempt to locate them more definitely or remove them, septicaemia would have been much more likely to have occurred, which would have done more harm than leaving the bullets where they were.

## REPORT ON MENTAL DISEASES.

BY HENRY R. STEDMAN, M.D., BOSTON.

### DISEASED CRAVINGS AND PARALYZED CONTROL.

UNDER this head Clouston<sup>1</sup> has recently given us two extended and valuable articles on the varieties, manifestations and treatment of dipsomania, morphinomania, chloralism, cocaineism and other conditions of defective control. They are instructive reading to both lay and professional readers.

He thus states the principles of treatment of dipsomania:

(1) We need legal control for many cases, without which nothing can be done. But at best we cannot possibly cure all cases of dipsomania for the reason that by the time a case is a dipsomaniac, he is often *ipso facto* incurable. You cannot apply the remedy in time. How can any period of enforced abstinence cure the atrophied brain-cells, and the hypertrophied membranes and neuroglia, and the degenerated vessels and lymphatics of the dipsomaniac of excess? It would, no doubt, be a great blessing to his relations and society to separate him from his fellows, but the process would have more the idea of an incurable asylum for a chronic lunatic than of a hospital for the treatment of dipsomania.

(2) Special asylums are needed, but the writer has not yet seen any institution that comes up to his idea of a true curative hospital for dipsomania.

(3) Every means that strengthens the bodily health, that restores all the functions of the brain and body to normal "tone" and working is good.

<sup>1</sup> Quarterly Journal of Insanity, July and October, 1890.

(4) "The special expedients," the "cures" and the panaceas generally are only temporary measures for special symptoms or crises. How can it be reasonably imagined that the highest brain quality, that of control, can be set up permanently by a few bottles of bromide of potassium or bark? No doubt such things are useful to allay temporary intolerable cravings, and to give the stomach and brain temporary substitutes for its accustomed stimulus.

(5) One of the best things we can do is to study the brain qualities, and especially the weak points of our children and our patient's children, so that by the prophylaxis of right conditions of life, by the formation of right opinion as to drink and its dangers, and by right "upbringing" generally in body and mind, the power of control may be strengthened, and cravings may be controlled before they become morbid. The most important thing by far, on the whole, in regard to dipsomania, in my judgment, is to prevent all such persons from acquiring a liking for drink, who, from their age, heredity, or neurotic diathesis, would be liable to have set up a morbid craving for it. It will be one of the problems of preventive mental medicine for the physician first to read the signs of the nervous and mental constitution along with the heredity, and then to say, "You shall not touch the dangerous thing. To you it is poison. There is something in you that will take fire if you do, just as surely as gun-powder will explode if you throw a match into it." Everything that can strengthen the sense of duty and the moral faculties generally, that can rouse interests in life and excite emotional enthusiasm, may save such persons if applied in time. Religion, love, business, family responsibilities and fear, may one and all cure a man on the verge of dipsomania.

As to morphinomaniacs:

(1) The habitual use of opium is in nine cases out of ten most injurious to the higher mental powers, and more especially impairs the volition.

(2) The dose has to be steadily increased till such an amount is taken as tends to impair nutrition and the trophic energy of the brain, to disturb the appetite and whole alimentary system, and ultimately to destroy the power of natural sleep.

(3) The craving set up by such excessive use of opium is one of the most persistent, intense and difficult to resist of any known morbid craving. It has no remission or periodicity in it.

(4) The nervous constitution of the patient has very much to do with the inception of the habit. It may be said generally that persons of the nervous diathesis, of nervous or insane or drinkers' heredity, all persons who feel and dread pain excessively, and most "excitable" persons, are especially liable to acquire the craving.

(5) Given or taken for insomnia or to relieve pain is the origin of most cases of morphinomania.

(6) It behooves medical men to take the constitution of each individual patient carefully into consideration before opium is prescribed, and to ask, "Is there any danger of a habit being set up?"

(7) As to the treatment of morphinomania the writer has little hesitation in laying down its principles. Help from without in the shape of skilled, strong nursing; control and never remitting companionship are needed in almost all cases. It is better and safer to undergo the short halcyon of absolute stoppage than

the more prolonged purgatory of tapering off. While this is being gone through, use the bromides, wines, every form of beef and peptonoids that the stomach or rectum will retain; bismuth, ice and counter-irritation for the gastric pain and vomiting; digitalis and strophanthus for weak and irregular heart's action. Paraldehyde or sulfonal should be used to obtain sleep, but their use should not be continued beyond a few nights. The great things to aim at are good nerve tone, firm muscles, a brown sunburnt skin, steady occupation, as much fat as can be put on, a sound moral sense all round, strengthened inhibition, and a dominating conviction that the drug is poison in any dose.

**Chloralism.**—Chloralism for a time threatened to become a rife craving, but chloral is becoming less liked and used than it was at one time, and will be numbered largely with superseded drugs. Chloral differs from other drugs, for which there is craving, and from alcohol, in this essentially, that its effect is not stimulant in any dose, small or large, but simply and only sedative and hypnotic. It creates no ideal state of mind, it simply produces forgetfulness and sleep. A craving for it, or a habit of it, is therefore a strange and altogether abnormal thing. Why any human body should crave a drug, whose taste is disagreeable, to produce sleep in excess of the normal time, is entirely inexplicable on any hypothesis except that which attributes an essential affinity between the brain and nervous action, not only to alcohol, but to all classes of stimulant, sedative and hypnotic drugs.

**Cocainism.**—The chief facts about cocaine in relation to cocainism are thus summarized:

(1) It is the acutest and most absolute destroyer of inhibition and of the moral sense generally, that we yet know.

(2) The morbid craving is very intense, and control is absent.

(3) The dose requires to be increased faster than that of any other such drug to get the same effect.

(4) The delirium and hallucinations of all the senses of single doses, become chronic in cocainism.

(5) Its immediate effects are more transient than those of any other such drug, but this does not apply to the craving set up.

(6) The treatment of cocainism consists in outside control of the patient, in stopping the drug at once, in careful watching, nursing, the use of every sort of food that will keep up the strength, and of the bromide of ammonium, brandy and wine, tea and coffee, and possibly a hypnotic, like paraldehyde or sulfonal, for two or three nights at least.

(7) A patient suffering from cocainism can be usually certified as insane so far as the presence of delusions are concerned, but he gets over these so soon and yet is so far from real cure, that certification and sending to an asylum is not a satisfactory process altogether. We need cocainism included in any special legislation for dipsomania.

The writer also considers among morbid cravings and paralyzed control, masturbation, sexual perversion, morbid indecision, etc., and finally sums up the whole subject as follows:

(1) That many morbid and hurtful uncontrollable cravings exist apart from those for drink, morphia, chloral or cocaine.

(2) That there is a distinct class of "inhibitory neuroses" that may be accompanied by little intel-

lectual or emotional disturbance. The objects of the morbid cravings are often accidental.

(3) Some of the most morbid cravings and examples of loss of control are found connected with the reproductive function, in regard to which, too, perversions of object are also very apt to accompany such morbid cravings.

(4) For the existence of many cases of such reproductive loss of control, prostitution is probably responsible, and the unnatural habit of masturbation for many more.

(5) The reproductive instinct is in some cases morbidly transformed into uncontrollable impulses toward suicide and homicide.

(6) Cravings to break and destroy, accompanied by little intellectual disturbance, that cannot be controlled, are often met with.

(7) The state of morbid inaction is often closely allied to morbid impulse, one sometimes taking the place of the other.

(8) There are cases where there is a morbid loss of control over general conduct, in ordinary matters, and cravings to do quite harmless acts.

(9) There is a morbid condition of brain automatism, apart from hypnotism, in which there is little or no power of inhibition, but at the same time no active cravings, the conduct being regulated by the will of others, or by chance suggestion from without or within.

(10) Loss of control often precedes for some time the other mental symptoms of an attack of active insanity.

(11) Inhibition may be lost in one direction only, while in most others it may be very strong, gambling being often an example of this.

(12) All brains must have some "excitement" to keep them healthy, the important question being how to select the kind of excitement that will not lead to morbid craving, and that can be easily controlled.

(13) Morbid indecision may be an example of paralyzed control.

(14) We may have morbid and uncontrollable muscular action, not purposive, and not attended by ideation or emotion at all.

(15) It is a fact in man's medical psychology, that control is almost always lessened at night or in the darkness as compared with the day, the night being the time for morbid indecisions, fears, superstitions, and a tendency to mistake the subjective for the objective, his higher powers then undergoing a process of partial "dissolution." Man, in fact, is a less evolved being as regards his inhibition at night than during the day, and his brain is then more liable to disturbance of the controlling functions in disease.

#### PATHOLOGY AND PATHOLOGICAL ANATOMY OF GENERAL PARALYSIS OF THE INSANE.

Investigators in this field are no nearer agreement on the vexed question of the starting-point of this disease.

Mendel<sup>2</sup> sums up his latest results as follows:

(1) In the *neuroglia* there is an increase of nuclei; spider cells increased in number and size. Both are found from three to four times as numerous as in health, all through the cortex, in the deeper layers and in the frontal and central regions especially. These lead in

the ventricular walls to thickening and roughening of the ependyma. The brain substance therefore degenerates, and sclerosis ensues.

(2) In the *vessels* there is an increase of nuclei (in the smaller ones). Dilated lymph spaces, cystoid degeneration, miliary aneurisms and colloid and hyaloid degeneration are also found.

(3) In the *ganglion cells* fatty and pigmented degeneration, contracted or enlarged nuclei, sclerosed and atrophied cells, dilated perivascular spaces, are always seen, especially in the frontal lobes.

(4) The *nerve fibres* are atrophied throughout the entire brain in central gray matter and cerebellum. This atrophy is also seen in epilepsy, senile dementia and alcoholic paranoia. We also find Lissauer's changes; altered intercellular tissue in the optic thalamus, with atrophy of ganglion cells. The cord is also involved in either the posterior columns alone; the lateral pyramids alone; the lateral pyramids and cerebellar pyramids, with intact posterior columns; and finally there are mixed lesions. These changes are not characteristic in themselves of general paralysis, but the diffuse nature of the process is the distinctive feature, involving as it does the cortex, white matter, cerebellum, etc.

He states the two theories:

(1) Primary degeneration of *fibres*; the changes in the vessels, neuroglia and ganglion cells being secondary.

(2) The process begins in the *vessels*, leading to inflammation in neuroglia. He exhibited specimens of isolated vessels in general paralysis and in healthy brain, proving marked changes in the vessels. Artificial general paralysis produced in dogs (dog and specimen shown) revealed no change in medullated fibre or in ganglion cells, but many nuclei in walls of vessels, dilated adventitial space and increase of nuclei. Vertigo, apoplectic attacks, etc., may occur early in the disorder, and are perhaps of vascular origin.

He finally gives us his own belief, namely, that the disease is first a disease of the vessel-walls. There is hyperamic stasis in the vessels, exit of blood-corpuscles, inflammation of neuroglia, which leads secondarily to destruction of the nervous elements. In short, there is a diffuse interstitial encephalitis, which leads to brain atrophy.

Schütz<sup>3</sup> describes in minute detail many fine sets of fibres with their connections, in central gray matter, giving diagrams and sections. This part is next in importance to the cortex in the way of complexity. He reports twelve cases of general paralysis. In all these there are changes in the central gray matter. There is a diminution of the longitudinal fibres from the third ventricle to the decussation; loss of fibres also in eleven out of the twelve cases from locus ceruleus to the nuclei of third nerve. Nuclear gray matter showed loss of reticulated fibres. Only the motor nuclei of nerves were affected.

He thinks that the morbid process in general paralysis begins with atrophy of the fibres, not inflammation. He fails to find inflammatory changes in the central gray matter. No increase of nuclei. In half of his cases newly formed vessels with thick walls were found. Ependymitis was a common complication. The fibres were permanently diseased in central gray matter. He does not find this loss of fibres in senile

<sup>2</sup> Proceedings Tenth International Congress. Neurol. Central., September 1, 1896.

<sup>3</sup> Anatomical Researches on Course of Fibres in Central Gray Matter, and their Disappearance in General Paralysis. Archiv. f. Psychiatric, xxi, 72, 1894.

dementia, chronic alcoholism or chronic paranoia; but at the same time does not consider it the essential change in general paralysis, although very common. Finally, these changes are the probable cause of part of the motor symptoms of general paralysis.

Zagari<sup>4</sup> has examined particularly the optic thalami of general paralysis, in which disease he finds two sets of symptoms, one slow and chronic, another sudden and transitory (aphasia, monoplegia). In the latter there is probably a sudden circumscribed change in the brain. Lissauer noted focal symptoms leading rapidly to death. He found in the optic thalami circumscribed spots of degenerated tissue, which he did not find in cases where these focal symptoms were absent. Monakow found degeneration in optic thalami after destruction of the cortex.

In brains of five general paralytics the hardened optic thalami shows no gross changes. Sections showed medullated fibres, spindle and stellate cells, fine and granular ground substance, and darker stained spots of compact tissue. In some, such spots took up most of the space, and here the cells were fewer, smaller and at times absent. These spots of degeneration were largely confined to the right thalami. They were in no case found in corpus striatum. Case I. Changes in the right optic thalamus and anterior left optic thalamus, also in corona. This patient had apoplectic and epileptic attacks during the last five months of his life. Case II. Anterior portions of both optic thalami involved, here consciousness was lost six months before death. Case III. Both optic thalami involved. Apoplectic attacks one year before death. Case IV. No changes found in optic thalamus. No attacks. Case V. Very few changes found. No attacks.

The extent and size of the lesions bore no relation to the number or severity of the attacks. He concludes that the optic thalami in general paralysis often the seat of peculiar changes, but is not prepared to state the relation between these changes and acute paralytic symptoms so confidently as does Lissauer.

Pick<sup>6</sup> finds changes that look like increase of nuclei in the long axis of the ganglion cells; no connection with the vessels. It is really a circumscribed swelling of axis cylinders, as sclerosis.

Kronthal<sup>6</sup> has investigated the condition of the capillaries in general paralysis, and finds degeneration coexisting with fibre atrophy. Degenerated blood capillaries were found in the seven brains examined, and in these all the capillaries were degenerated in frontal lobe. In four out of five cases degeneration found in cerebellum; four out of seven, in occipital region; in two cases, in central convolutions; in two out of three cases where it existed, in the temporal; and one out of three, in the parietal. There are two forms of degeneration; one begins with increase of nuclei, in the other the walls thicken. There are also mixed forms.

#### THE SOMATIC PHENOMENA IN HYPNOTISM.

Tamburini,<sup>7</sup> in a very thorough study, reaches the following conclusions:

(1) The phenomena of the so-called stages, lethargy, etc., may be verified in a limited number of cases independently of suggestion.

(2) These phenomena do not justify division into separate stages, as they are often mixed and confused,

represent only increased reflex excitability, due to different nature, intensity, or duration of stimuli.

(3) These phenomena are not characteristic of grand hypnotism, but are seen apart from it in grand hysteria.

(4) When seen in hypnosis they represent symptoms proper to hysteria, which are put in evidence by excitation of reflex excitability in hypnotic state.

(5) Hypnotism is not a provoked neurosis, but its pathological phenomena are due, not to hypnosis *per se*, but to its calling out latent symptoms of hysteria, of which it is an exquisite revealer.

(6) Hypnotism is a simple state of provoked sleep, not pathological; but it produces increase of reflex excitability and marked increase of suggestibility.

(7) Phenomena in hypnotism can be varied infinitely according to patient. They are due not to hypnotism, but to pre-existing morbid conditions in the individual.

(8) Innumerable forms of hypnotism are not really due to it, but to varying suggestions or to varying pre-existing pathological conditions (hysteria?).

#### STUPOROSE INSANITY, CONSECUTIVE TO INDUCED HYPNOTISM.

Nolan<sup>7</sup> swells the accumulation of cases of insanity following hypnotism by reporting a case of stupor in a corporal of irregular habits who, when physically unstrung by dissipation of the grossest kind and in a state of extreme nervous tension, was hypnotized at an entertainment. Within a few minutes he was dead to his surroundings, and at no time afterwards had he the slightest recollection of any occurrence during his trance. Intense frontal headache, extreme languor, "confused and queer" feelings, confined him to the hospital immediately afterwards for a time, which he left in a "stupid" condition. He was again hypnotized by a woman who gave a performance, with more disastrous consequences, and became dazed, vacant, irrational and suicidal, and was finally committed to an asylum, where he reached the following condition a month or two later: "Stands erect and rigid; expression vacant; eyelids drooping, with intermittent blinking movements; eyeballs rolled upwards and slightly inwards; pupils widely dilated, sluggish reaction to light and accommodation; nostrils expanded and snuiling; lips pursed and tremulous; arms limp; hands rhythmically beating thighs. He is silent, only answering after repeated questioning. When shaken and spoken to, there is a very gradual awakening to a condition akin to "expectant attention." When unnoticed there is an increase in the frequency and intensity of the automatic movements, and a relapse to the stuporose state. Memory, defective; reflexes increased. The condition designated by Charcot, "hyper-excitabilité neuro-musculaire," is well marked in the facial, less so in limb muscles. An hallucination appeared at times. He gradually improved, and was discharged recovered five months from the date of the onset of the attack. The undue length of the period of stupefaction, during which volition and consciousness were partially dormant and irresponsibility complete; the uncommon character of the hallucination; the suicidal impulse and insomnia, — were the prominent features of the case, which the writer thinks calculated to shake our confidence in the assurances lately so common, of complete immunity from danger in hypnotic experiments.

## Reports of Societies.

### SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

GEORGE H. MONKS, M.D., SECRETARY.

REGULAR MEETING, Wednesday, March 4, 1891,  
Dr. A. T. CABOT in the chair.

Dr. D. W. CHEEVER reported a case of

#### COMPOUND DISLOCATION OF THE HIP.<sup>1</sup>

Dr. S. W. LANGMAID spoke of a patient of his, a girl, who had been under his care some years before at the Children's Hospital for a compound dislocation of the hip. Dr. A. T. Cabot, under whose care the patient subsequently came in the hospital, showed this patient to the Society later in the evening. Dr. Langmaid said:

I can state briefly the history of this case while it was under my care, but it is from recollection which I have not refreshed. The girl had received an injury, but what kind of an injury or how it was received was not made out at the time, as I remember. There was, however, some story of an ice-wagon having run over her or against her. When I saw her, which was in the Children's Hospital, the injury was very like what Dr. Cheever has described; only the laceration of soft parts was much more extensive. The head of the bone, the neck and trochanter lay flat upon the surface of the abdomen with the soft parts of that region closed around, but the wound extended through the groin and down towards the vulva. As in Dr. Cheever's case, there was no pulsation in the ankle or anywhere in the leg. The question which presented itself to my mind was, what is the injury to the great vessels, and I think a very careful dissection was made previous to any attempt to reduce the dislocation. The first thing that was found was a blue spheroidal-shaped affair, first taken to be a gland, but found to be the femoral vein. The artery was found to be a white cord. The dissection having been accomplished, the dislocation was easily reduced by manipulation, and after a time the pulsation returned to the ankle. Then came the question, what should be done with the head of the bone. In all previous smaller compound dislocations I had followed the teaching of the books as I had understood it, and had made resections. In this case it seemed to me that the drainage could be perfect, and the only question was with regard to keeping the dressings free from the discharge of urine, because the wound was so extensive in the groin, but as this drainage was so good I concluded not to make a resection but to return the head of the bone, which I did. The drainage-tubes were put in the wound, and such an antiseptic dressing as could be made was applied and a splint outside, and then the child was put to bed. There were two secondary hemorrhages, the dates of which I cannot recall. The wound was free from hemorrhage when closed. One of the secondary hemorrhages was severe, and it was not thought that the patient could live. The girl manifested very great vitality, and this had much to do with her recovery.

Dr. CABOT said that he first saw this case when he took charge of the ward under Dr. Langmaid's service. At that time there was an extensive suppurating wound in the groin, the head of the bone was in

place, and the limb was fixed on a posterior wire splint such as he has described for excision of the hip, and for aggravated hip disease.

The subsequent history was that of any large wound in which drainage had to be kept up. The wound gradually healed by granulation. As a final result, the leg was firmly ankylosed in a slightly flexed position.

[The patient was then shown to the Society. She could walk up or down stairs, not dragging the lame leg, but raising one foot and then the other from stair to stair. She walked with a perceptible but not an aggravated limp.]

Dr. D. W. CHEEVER: I would call attention to the fact that the only case of recovery of those that I reported was in a child, a lad of seventeen, and of course it will appear in connection with this very interesting case that has just been shown that probably the youth of patients has a good deal to do with the recovery. I was not aware of the existence of this case, and I am very glad to see the patient.

I think that the fact that there was so large a laceration going down into the perineum placed the case in a little different light as regards the propriety of excising or not excising the head of the bone from one where there was a button-hole through the groin with the head pushed out in a large muscular man, and no chance for drainage unless an opening was made. Almost all these cases die. It is difficult to see how it can ever be otherwise. The force applied must be so immense, that other organs can hardly escape; and, although I have no record of autopsies in the cases I have quoted, and know of none, yet I cannot help thinking that several of the patients who died in five to twenty-four hours, probably received other injuries.

The very remarkable fact about my case is, I think, that the man should have a hemorrhage taking place behind the peritoneum, a slightly lacerated aorta, and dislocated vertebrae partially torn off near the cauda equina together with this dislocation of the hip, without ever being in a state of collapse. He was injured down-town, and brought to the hospital by the police. I happened to be there and saw him at once, and his condition was very good indeed. He was perfectly conscious and not in a state of excessive shock. His temperature did not fall to 96° until after he had been kept etherized a good while. That, I think, is not uncommon after other operations. Many patients will start to have an operation done with normal condition, fall to that degree of temperature, and then come up again; but why he should have done so well from about twelve hours after the injury to about thirty-six hours after the injury seemed surprising considering the great changes which had taken place in the internal organs at that time. Most of the authors I have quoted are of what might be termed the older class, with the exception of Simpson and Ashhurst; and most of their experience and teaching has been before the antiseptic period. How far that may modify future treatment in these cases, of course time only can show, and I am not prepared to say that it might not be a perfectly successful and justifiable operation to reduce a dislocation in an adult and to try antiseptic methods without going through the mutilation of an excision. The ancestor of our present Dr. William Juggalls, who I think practised in Chelsea, and had the very remarkable case many years

<sup>1</sup> See page 523 of the Journal.

ago, which was afterwards put in Sir Astley Cooper's work, reduced the head by manipulation. The patient lived three weeks, and died from exhaustion and excessive suppuration. It seems as if that case might have been saved by the same methods with the antiseptic treatment added.

These cases, of course, will always be very rare. I think it is very important that all should be put on record that do occur, and, if possible, some rule should be formulated for the guidance of the surgeon who happens to be called to such a terrible accident where several questions present themselves to him for immediate decision and where the precedents are so very few. Of course with this accident, amputation is hardly to be thought of; because if the accident is severe enough to cause extensive laceration, probably the patient would not survive a primary amputation at the hip-joint, especially an adult probably would not, and then we should be reduced to the important question whether we shall cut off the head of the bone, or put it back into the socket, and hope to get anchylosis and a good limb which seems far preferable to excision. I trust that these three cases occurring here may lead to the looking up of other cases, and perhaps to some definite knowledge on the subject which apparently does not exist now. Most of the books on surgery dismiss compound dislocation of the hip as a thing so improbable that they only allude to it as something that has never occurred or is not likely to occur.

DR. S. N. NELSON showed

A PATIENT IN WHOSE BODY FOUR LARGE PISTOL-BALLS WERE LODGED, ONLY ONE OF THEM HAVING BEEN REMOVED.<sup>1</sup>

DR. O. K. NEWELL: I think this case is a very interesting one, and especially interesting to me as I happened sometime ago to go pretty thoroughly through the subject of bullet-wound treatment, and claimed the principle which I believe was established here by Dr. Beach in bullet-wound treatment, and which I think is not to-day carried out in this country. I think this case illustrates beautifully the harmlessness, as claimed now by I think a majority of military surgeons in Europe of a bullet fired at long range. I regard this case as a brilliant one in every way, and the only criticism that I would like and feel in duty bound to offer is that it would have been just as well, as the case proves, not to have probed for the bullets at all. As to the probable location of the ball I think it is absolutely impossible to say whether the ball was in one position or another. In the Warren collection one case in particular is shown where the ball was received in the back over the ribs and the natural inference would have been that it was in that vicinity, but it was found to have travelled around the ribs and was attached and hanging from the parietal layer of the chest-wall afterwards at the autopsy. Experience has shown that the slightest contact of a bullet with any small body may give the largest possible deviation to its course. It seems to me that all the evidence thus far shown which should guide us in the treatment of bullet-wounds, indicates that the proper method of treatment is to let them absolutely alone, to disinfect the external surface as thoroughly as possible, and not to complicate the chances in any way other than that. One French surgeon even goes so

far, and he reported to the *Gazette Hebdomadaire* a large number of cases, as to allow bullets of 22 calibre to remain in the metacarpal bones, stating that that was a safe way of treating the trouble. It was found that the bullets did no more harm than a tooth-filling. I think we see in this country almost daily in the papers accounts of cases, and I am keeping track of them now, where the first step taken is to probe for the ball and try to find it, and that in special instances is a procedure without advantages. This does not apply to cases with special indications, such as some brain and abdominal wounds.

DR. D. W. CHEEVER: I should like to ask Dr. Nelson what clothing this man had on.

DR. NELSON: The shooting was in the month of May. He had on a shirt, undershirt, vest and a light coat.

DR. CHEEVER: Those were all shot through?

DR. NELSON: Yes.

DR. CHEEVER: I understood that the wounds healed without suppuration?

DR. NELSON: Yes.

DR. CHEEVER: How soon?

DR. NELSON: There was scarcely any discoloration to the second dressing on the third day. The last dressing was on the sixth day. I inserted into the wounds a fine uterine probe a short distance only, to find the direction the balls took, but this was not done with the idea of probing for the balls in the ordinary sense.

DR. CHEEVER: Was any attempt at irrigating the sinus made?

DR. NELSON: No, sir. Cotton wet in sublimate solution was put on the probe and passed through the skin, but no attempt at irrigation as such was made.

DR. CHEEVER: I only ask these questions for the reason that I suppose it has been long recognized that balls do no harm in many places; but it has always been thought that the importance of probing and washing out or irrigating was due to the fact that almost always some foreign substance was carried in which was decomposable, and more likely to set up trouble than the ball itself, especially particles of clothing, and frequently in battles fought, as many of our battles were, in forests, chips and twigs and all sorts of substances. It is a well-recognized fact I think from our experience here that the very many fatalities which have occurred in the form of tetanus after the use of the toy pistol where there is no ball, have been due to the decomposition of the pieces of yellow paste-board, which forms the shell and contains the explosive material, which shot as it almost always is, into the palm of the hand as the boy holds the pistol, enters beneath the palmar fascia and remains there unsuspected, is not found by probing or in any other way because it is soft, and subsequently brings on septic infection and tetanus as has occurred in so many cases. This class of injuries would seem to prove the wisdom of incising or exploring or irrigating or being reasonably sure that other substances not lead, but decomposable substance, were not buried in the tissues, and that seems to me the strong argument for searching wounds instead of doing them up at once.

This case is an extremely interesting and happy one, and it is to be supposed and hoped that the balls in the body now are not in contact with bone. If they are in contact with bone the history of most cases

<sup>1</sup> See page 536 of the Journal.

show that they may be heard from yet, but if they are lying away free from bone they will not provoke necrosis or anything of that kind.

DR. NEWELL: I should like to say one thing more in regard to a point Dr. Cheever has brought up. I think what he says is true and recognized in regard to treating bullet wounds at short range, that you may get powder and clothing or something else in the wound. An important fact has been brought out by an American surgeon, who after having a case of recovery from bullet-wound of the stomach without interference in a case in which he knew the stomach to be full at time of shooting, experimented by having stomachs filled and bullets shot through them, and he found that the stomachs did not leak. The ball is conically rounded and scarcely leaves a mark in the clothing. In most all of the modern bullet wounds at long range, nothing enters but the ball. Of course with the large balls used in the War of the Rebellion, the larger slugs, most anything would be carried in. I think this question in its new phase has come up since the Franco-Prussian War, when smaller gauged arms and balls have been used, and especially in the treatment of revolver wounds.

DR. F. B. GREENOUGH: I have not seen any bullet wounds since antiseptic surgery has come up. In 1865 I was at the Lovell United States Hospital at Portsmouth Grove, R. I., and in charge of two wards of sixty beds each, while they were fighting around Petersburg, and there I saw a good many bullet wounds. In those days we thought it was not only the danger of foreign substances being carried in, but that the fact of a bullet, especially a rifle ball, going through the flesh bruised it or committed a certain amount of injury that must result in slough. I remember that there was a gentleman who came down from the country to take the position of acting assistant surgeon, and that he treated some of the men brought in wounded from Fortress Monroe by sewing up the point of exit and entrance and his result was not very good. I should like to ask Dr. Nelson if there was absolutely no suppuration at all?

DR. NELSON: There was absolutely no suppuration. There was only a slight sanguinous discharge which discolored the first dressing.

DR. CHEEVER: It is a subject I am very much interested in. Like Dr. Greenough I was in an army hospital a good while and saw a good many wounded during the war. Suppuration was the invariable rule at that time. Six weeks was the common time for a gunshot-wound which went through the flesh to get healed. It healed by granulation. Septic infection also was quite common. The elder Larrey, the surgeon of the First Napoleon, and who went through almost all his campaigns with him, mentions as a remarkable fact in his work on surgery, that he once saw a gunshot wound heal without suppuration, and of course his experience must have been of many thousand cases. Up to a recent date, I do not know but now, it is generally expected that the gunshot wound is a lacerated, burnt, tortuous tract which is pretty sure to heal by second intention. Whether or not it absolutely gives rise always to pus cells and to microbes, may or may not be true; but the rifle ball bores and twists, splits bone longitudinally instead of going through it. The old round ball went through the bone, while the other splits it into fragments. The result is different from what it used to be, and it

is doubtful I think as yet, whether it is perfectly safe to leave a gunshot wound without investigation, without irrigation, without the search for foreign bodies even more important than the ball.

I made the statement that if the ball was in contact with bone, it would probably be heard from. I should like to verify that by two rather remarkable cases. One was brought to the City Hospital some nine years after the close of our late Civil War, and the patient had all the appearance of hip disease,—the retracted and shortened limb, wasted muscles, peculiar position of the limb, etc. He had an unhealed gunshot wound in the nates. He was etherized, and the wound freely incised and the tract explored; and after a good deal of cutting through deep tissues, the ball was found lying on the ilium, with necrosis behind it. The ilium had not been perforated. It was lying on it.

Another case which was quite remarkable was that of a little child three or four years old, who was brought to the hospital, having been shot by her father, who had also shot himself, and who was brought in at the same time. The father succeeded in killing himself, for he died two or three hours after entering the hospital. He had put the pistol at the ear of the little girl. The ball entered the meatus externus, and probably was lodged in the temporal bone. Slight probing and washing out seemed to reveal the fact that it was not safe to go after it. The child was kept in the hospital all winter. Paralysis appeared, showing that the nerve had been injured in the canal where it passes through the bone. The child recovered and went out. The ball was in contact with, or lodged in and about, either the temporal bone or a portion of the sphenoid. Nine years afterwards I was sent for to see this child, and found her grown up. She showed me the ball, and said she coughed it up two or three days before.

DR. NEWELL: I think there is a little misunderstanding about this subject. I suppose the Society is aware of the fact that it is demonstrated by hundreds and hundreds of cases that these bullet wounds, even though they may "split-up bone," etc., are just as safe if treated at once antiseptically as any aseptic wound. They are so confident of this in Europe that soldiers are supplied with absorbent cotton, and are directed to clap this aseptic cotton over the wound so that the surgeon will find them prepared in the best way to have a good result. I have collected over a hundred cases of wounds treated in this way with absolutely no suppuration, and I have seen personally over twenty cases, with perfect results. Two wounds were through the palmar fascia, and gave no trouble. The dressings were done under spray. The cases have never reported any trouble since that time.

DR. G. W. ALLEN read a paper on

#### THE TREATMENT OF ACUTE URETHRITIS.\*

DR. GREENOUGH: I have no question about the advantage of the antiseptic treatment, but I have a good deal of question about its applicability in very acute cases of gonorrhoea. As far as my experience goes, there are a great many cases in which the patient cannot use bichloride or permanganate or any other antiseptic in even a very mild injection. I think there is a very good chance, if you continue with your injections, of having cystitis, epididymitis and a series of symptoms which may be very serious. At least, that

\*See page 525 of the Journal.

has been my experience. As for aborting gonorrhœa, we used to try that twenty years ago with strong injections of nitrate of silver. I have seen cases that apparently did succeed. Our fellow practitioner said: "I have cured a case of clap in four days." Such cases I think, are those which come to you, and say: "Doctor, I cannot see a woman without getting the clap." You examine and find granulation tissue or slight stricture, and when the man has connection, it starts it up afresh, but it is not a fresh injection. I do not doubt what Dr. Allen has done with irrigations or injections, but I think it is a very dangerous thing to preach up to the general practitioner. I think there is a good deal of harm done by it, as I think there was a good deal of harm done by Dr. Otis's teaching in regard to strictures of large calibre. In Dr. Allen's hands this is all very well, but I do not believe in telling the general practitioner that he can abort a fresh attack of clap with bichloride injections.

DR. ANKER POST: There is one thing in the paper that pleased me especially. In spite of Dr. Allen's very laudable desire to use the antiseptic injections, and I agree with him fully in regard to their value, he has made an exception in just those acute cases to which Dr. Greenough refers. There are a certain number of exceedingly acute cases that must be handled as you would handle an acute inflammation in any other part of the body. You must treat them with antiphlogistic principles, if you choose to say so. You would not be content to wash them out with an antiseptic solution. The very method that you take, does increase the irritation and the inflammation. I am repeating simply what Dr. Greenough has said. I do not wish, in the least, to undervalue the antiseptic applications. I believe in them thoroughly, and have seen cases enough where their use has been brilliant, but at the same time I have others where I think their use has been unfortunate, not because they were antiseptics, but because they were wrongly applied. Dr. Allen is sufficiently my friend, I am sure, to let me say what I please in regard to his cases. I am a little surprised that he should bring forward cases of recurrent clap as arguments in favor of any course of treatment in acute disease. It seems to me that any method of treatment which a man desires to advocate, he must advocate on the ground of its value in virgin cases. The cases of recurrent inflammation can be treated with much less care, and they get well; at least, they recover up to a certain point much more easily than the majority of primary cases. Of course, a great many of the secondary cases are very severe. It may be just as much of a triumph to close them up early; but in using them as arguments in favor of a certain course of treatment, it seems to me that the argument falls short of the necessary proof.

DR. ALLEN: In regard to these very acute cases I did make an exception of them, as Dr. Post said, but in cases not quite so acute it has been my experience that I could use corrosive sublimate, and that a copious thick purulent discharge was very soon cut down and became thin and subacute. In regard to the cases mentioned in the paper not being first cases I am sorry that I could not report any such. I do not think I ever saw more than two or three first attacks of gonorrhœa within the first few hours. It seems to me the whole point in this abortive treatment is to get them almost immediately; I think twenty-four hours is probably too long, and it is a question whether it is

not necessary to get them within twelve hours. I doubt if many physicians often see first cases of gonorrhœa within twenty-four hours; they almost always fool around a few days before they go to the doctor. These cases seemed to be acute infectious urethritis with a period of incubation of three to six days, with a discharge containing gonococci. It seemed to me that they were true cases of gonorrhœa, and not simple exacerbations. One of them, for instance, was a second case of gonorrhœa whose first attack had been long, lasting months, this second attack coming two or three years later. I saw him within twelve hours, and I only saw him once, irrigated him once with a bichloride solution, and did not see him for six months, and when he came back he had the third attack, but said the second attack was stopped almost immediately. In this third attack I did not see him until after forty-eight hours at least, and this time it went through the long course, although the treatment was the same. Another had had his first clap two or three years before, and four days after going with a woman he had this discharge containing gonococci. There had not been a symptom of any kind for two or three years, although he had been around rather promiscuously. I think the important point of the whole thing is to get them very early, within a few hours, and that when twenty-four hours have passed the chances of cutting them short are small, and it is rare to get a first gonorrhœa as early as that.

DR. CABOT: I should like to ask Dr. Allen if he gives internal treatment.

DR. ALLEN: Nothing but diuretics. If one had to depend on internal treatment, and could not for some reason use injections, copaiba is, I think, excellent.

DR. CHEEVER: I should like to say a word from the old-fashioned standpoint on these cases. I cannot help thinking how much better it would be if mankind, and womankind also if possible, were as afraid of the clap as they are of syphilis. I think I have arrived at the conviction that the consequences of gonorrhœa are even more serious than those of syphilis.

If we had a case, in which we could do just as we pleased, what would we advise? Well, I should advise that the patient go to bed and stay there for some considerable time; that he take saline laxatives, that he take antacids, diuretics and demulcents and hot baths, and in all probability the disease would subside without any sequelæ of any kind and very speedily indeed.

I say this on some experience, because I was placed once where I had complete control of patients in the hospital of one of our institutions in the harbor many years ago. We had the worst sort of people, sailors and prostitutes. The sailors arrived with very acute cases of gonorrhœa, and of course no nonsense or indulgence was shown in treating them. They were put to bed, treated as I have described, and in addition to it copaiba was used pretty freely (injections being rarely used), and the results were more speedy and comfortable in every way than any I have seen since. We cannot impose this on private patients, but that, in my opinion, would be the true way to treat the disease. I have great faith in the virtues of copaiba in proper mixtures, although they are very disagreeable to take. Injections, if the doctor can give them, are all right. If the patient gives them to himself, I think he is very liable to do himself harm.

DR. S. J. MIXTER demonstrated

A NEW METHOD FOR CUTTING GRAFTS FOR  
THIERSCH'S SKIN-GRAFTING.

A full description of the apparatus used and of the method of employing it will be published later.

AMERICAN MEDICAL ASSOCIATION.

THE FORTY-SECOND ANNUAL MEETING, HELD AT  
WASHINGTON, D. C., MAY 5-8, 1891.

(Continued from No. 21, page 512.)

SECTION FOR PRACTICE OF MEDICINE AND PHYSIOLOGY.—THIRD DAY.

DR. J. S. NOWLIN, of Shelbyville, Tenn., read a paper on

EPIDEMIC CEREBRO-SPINAL MENINGITIS.

The disease is in reality not an inflammation, but is due to malarial poisoning, acting primarily on the nervous system. This idea is not new, and is borne out by the nervous symptoms, and by the great benefit to be derived from quinine. This drug should be administered freely, by subcutaneous injection, and should be given also as a prophylactic.

DR. DOCK did not believe that the disease was malarial; it may occur anywhere, but malaria may closely simulate cerebro-spinal meningitis. A differential diagnosis is of great importance, with a view to treatment, and may be made by microscopic examination of the blood.

DR. W. B. DAVIS, of Cincinnati, read a paper on  
THE PREVALENCE OF ALBUMINURIA IN PERSONS  
APPARENTLY HEALTHY.

It was formerly considered that albuminuria was pathognomonic of nephritis, but such is not the case. It may occur periodically, or even in a few cases continually, in persons in perfect health. This was agreed to by others present.

DR. J. H. JENKINS, of Tecumseh, Mich., sent a paper on

EUPHORBIA PILULIFERA IN SPASMODIC ASTHMA.

He had used the fluid extract with very good results.

RESULTS WITH TUBERCULIN.

DR. KARL VON RUCK, of Asheville, N. C., gave the results with twenty-one cases. If properly given there need be no unpleasant results. The heart became more irritable during the course of the treatment.

DR. S. P. KRAMER, of Cincinnati, thought that tuberculin, when properly understood, would be found to be the best treatment for certain cases of tuberculosis.

DR. OSLER said that the results with tuberculin at the Johns Hopkins Hospital had not been encouraging. In five out of twenty-four cases, where the extent of the lesion was slight, there was some improvement. In other cases the disease appeared to spread under its influence.

DR. ECCLES thought that Koch would yet discover a cure for tuberculosis.

DR. WELCH described the microscopic appearances of the diseased tissue during the injections. He thought it possible that there might be a tendency in tubercular

foci to become encapsulated as a result of the treatment.

DR. VAUGHAN had injected a substance obtained by filtering colonies of a bacterium entirely different from the tubercle bacillus, and had obtained a reaction and apparent improvement.

DR. CHARLES H. SHEPARD, of Brooklyn, read a paper on

THE ACTION OF THE TURKISH BATH IN DISEASE.

The value of sweating is often underestimated, and much relief may often be obtained, especially in some diseases, such as phthisis, nephritis, different skin diseases, etc.

DR. GEORGE DOCK, of Galveston, Texas, read an abstract of a paper on

THE MALARIAL PARASITES, AND THE FORMS OF  
DISEASE IN WHICH THEY OCCUR IN TEXAS.

Out of seventy-six cases of suspected malaria he had found the plasmodium in the blood in forty-one. The others included several diseases, the symptoms of which might in a malarial country be mistaken for malaria. As large doses of quinine would be contraindicated in some of these cases, a differential diagnosis is important, and may be made by an examination of the blood.

DR. OSLER said that typhoid fever was often very difficult to distinguish from malaria. The examination of the blood was a valuable diagnostic means, and he noticed that in Germany the discovery of Laveran was at last receiving the attention due it.

DR. W. J. HERDMAN, of Ann Arbor, read a paper on  
ELECTRICITY THERAPEUTICALLY CONSIDERED.

The advantages to be derived from electricity are numerous. It is not necessary for the physician to make his own electricity; if he can be connected with an electric light system he may safely use the supply.

The Committee appointed last year to investigate the fevers of the South, was continued until next year.

SECTION OF OBSTETRICS AND THE DISEASES OF  
WOMEN.

A very large number of papers were offered in this Section. This was alluded to in the opening address by the Chairman, DR. CHARLES A. L. REED, of Cincinnati, who favored a division into two sections, Obstetrics and Gynecology.

DR. H. D. FRY, of Washington, read a paper on  
THE PREVENTION OF PTERIAL CONVULSIONS BY  
THE INDUCTION OF PREMATURE DELIVERY.

Considering the large percentage of premature children who live, if properly attended to, and the dangers to both mother and child in cases where toxic symptoms from uræmia exist, there should generally be no hesitation in inducing labor. The presence of albumen in the urine is not alone sufficient evidence of danger to warrant interference. The best method is the insertion of an antiseptic bougie between the uterus and membranes.

DR. LEWELLYN ELLIOT, of Washington, read a paper on

SPASMODIC STRICTURE OF THE PRETHRA FOLLOWING  
LABOR.

This is a rare complication, and may differ in its

course, and may be painful or painless. It may arise from injuries or from nervous disturbance or rheumatism. He reported two cases, both occurring on the seventh day. Treatment must be directed to the cause of the trouble, but also local astringents and caustics are of use.

DR. J. S. STONE, of Washington, read a paper on

#### CAN THE GYNECOLOGIST AID THE ALIENIST IN INSTITUTIONS FOR THE INSANE?

There are many cases in hospitals for the insane where the rational treatment of the nervous disturbance should be directed to the organs of generation. By the failure on the part of some alienists to recognize the connection between the two, many women are unnecessarily deprived of their liberty. Some provision should be made by which this unfortunate state of things could be rectified. The author cited cases in which insanity had been cured by operations on the genital organs. Similar cases were reported by others, and suggestions offered looking towards inspection of cases at asylums.

DR. E. S. McKEE, of Cincinnati, read a paper on

#### THE CLINICAL TEACHING OF OBSTETRICS IN AMERICA.

The lack of practical teaching of this branch is one of the most noticeable failings of most American medical schools. This is due partly to the short time of medical study, and often to the small size of the town in which the school is situated. There has been an improvement during the last few years. A short time ago ninety-nine per cent. of the medical graduates of the country had not seen a case of labor at graduation. In giving his ideal, the author described very nearly the instruction as given in the Harvard Medical School. He urged the Section to induce the American Medical Association to take a strong stand in advocating better methods throughout the country.

In the course of a paper on

#### THE TECHNIQUE OF SUCCESSFUL ABDOMINAL AND PELVIC SURGERY,

by DR. W. H. WATHEN, of Louisiana, the reader said that at the present not only was too much laparotomy being done, but that too many men were doing it. Men who knew nothing about the diagnosis and pathology of abdominal and pelvic diseases, or about the best technique to be followed, and who had few facilities for doing such work, were undertaking it on all sides. Even by the best men cases were operated on in which the indications did not justify it. Patients were too often made worse after being mutilated in a way which admitted of no repair. In discussing various points in operative technique he said that some operators who talked a good deal about antisepsis did not know how to be surgically clean, because they had not learned to appreciate the value of cleanliness in every detail before and during an operation. The patients sometimes suffered more after an operation than before it, because of the extensive adhesions induced by uncleanness, antiseptics or traumatism committed by a careless operator. He believed adhesions would be fewer if antiseptics were absolutely excluded from the operating-room and were not even used for the instruments and hands. Antiseptics are likely to so irritate the peritoneum as to cause few or many adhesions. The practice of trying

to drain the peritoneal cavity by introducing strips of gauze or wick into the tube to its bottom, or allowing shreds to enter the cavity, as practised by the German laparotomists, was bad surgery, and might easily be the means of introducing septic matter.

DR. W. M. POLK, of New York, read a paper on

#### CONSERVATISM IN DEALING WITH THE APPENDAGES.

He assumed that the larger number of workers in the field of uterine disorders would agree to the propriety of operation, where in spite of the proper application of non-operative measures, a sufficient amount of disease persisted in the uterine appendages to render the possessor a chronic invalid. It was idle to suppose that with our present means of diagnosis, the conditions presented by chronic disease of the tubes could be differentiated short of an exploratory incision. The statement could be substantiated, that not infrequently tubes and ovaries were removed which were distended with purulent fluid, and yet for months prior to operation, no symptoms pointing to a purulent accumulation were present. The question, therefore, as to the contents of the diseased tube or ovary was, short of operation, unanswerable in many instances.

After classifying the conditions which may exist in the appendages the author summarizes as follows: In cases of chronic disease of the appendages, incisions should be in the nature of "exploratory" incisions. The question of removal should be in the main left for determination after the organs had been exposed. The condition of the ovary should be the main factor in determining the question of procedure. If need be, this might be determined by exploratory incision of the ovary. If the ovary contain pus, it and the tube should be removed, as in the classic "Tait's operation." If the tube contain pus the ovary being free from pus or disseminated cystic degeneration, the operator is at liberty to recommend either the last-mentioned operation, or else the partial amputation of tube leaving ovary. The same rule applies in cases of hydro-salpinx and hæmato-salpinx; this, as would be seen, preserves to the patients ovulation. Cysts of the ovary do not indicate removal provided they are not generally diseased and the cyst can be enucleated. Hæmatoma of the ovary is a possible exception. Ovaries enlarged from congestion, as in misplacements, need not be removed. Tubes with open infundibula, even though adherent and affected with parenchymous salpingitis, and endosalpingitis, do not demand removal, the exception being when one opens into a pus cavity. A tube whose infundibulum is closed may be opened, cleansed, its inner and outer coats coapted and sutured, provided it does not contain pus and possibly old blood. Adhesions do not warrant the removal of the tubes and ovaries unless they be so dense that in breaking them the appendages are seriously injured. This presupposes that the appendages in themselves are not sufficiently diseased to demand removal.

DR. A. J. C. SKENE, of Brooklyn, in a paper on the

**PATHOLOGY AND TREATMENT OF CHRONIC OVARITIS,** while admitting that the organs were not necessary to existence and that they could be removed with comparative safety, deprecated the practice of taking wholesale advantage of this fact; moreover, many of the cases were not benefited by the radical interference. Changes of some kind always supervened, and but few

patients were left entirely well after such surgical measures. He would only advocate removal of the organs where there coexisted structural changes and prolapse. He then enumerated the therapeutical agents and measures which should have thorough trial, and believed that such conservatism would often disappoint the gynecological operator.

#### UNSUSPECTED ECTOPIC GESTATION.

DR. H. F. FORMAD, of Philadelphia, gave the results of a series of observations which by virtue of his position as coroner he had been able to make in a large number of post-mortem examinations on women, with a view to ascertaining the cause of death in cases where ante-mortem diagnosis had not been made. Since commencing careful investigation, he had come across thirty-five cases of unquestionable ectopic gestation. Of these, there had been but one ovarian and three interstitial, the remainder being intra-peritoneal. There was no instance of extra-peritoneal pregnancy. In none of these cases had the condition been diagnosed when a physician happened to be called in previous to death. The histories showed that all the women had been engaged in hard work, subjected to violence, or were laboring under special excitement. His conclusions were that the condition of extra-uterine gestation was a much more common one than was supposed, and that a certificate of heart disease, or any other such vague statement frequently, though unwittingly, covered up the real facts.

#### SURGICAL SECTION. — THIRD DAY.

DR. EDMUND ANDREWS, of Chicago, read a paper on

#### CADAVER STUDIES ON THE REMOVAL OF THE SEMILUNAR GANGLION THROUGH THE FLOOR OF THE CRANIUM.

Relapses of facial neuralgia, after stretching or resecting the nerve for its relief, are very common. Even after resection, relief is sometimes obtained temporarily by a second operation, loosening the end of the nerve in the cicatrix. The author thinks that this neuralgia is often caused by a neuritis, which, beginning at the periphery of a nerve, travels upwards, finally affecting the semilunar ganglion. With a view of reaching this ganglion work has been done on the cadaver, and a method established which he considers the best for its removal. An H-shaped incision is made over the zygomatic arch, which is sawed through at both ends, and turned down with the lower flap. The coronoid process is then sawed through and included in the upper flap. The inferior dental and gustatory branches of the inferior maxillary nerve are reached through the masseter and internal pterygoid muscles, and followed up to the foramen ovale. The ganglion is reached by trephining the edge of the foramen. The ganglion is dissected from the dura, to which it is firmly attached. A similar operation has been twice done by Rose, of London.

DR. LAWRENCE TURNBULL, of Philadelphia, read a paper on

#### DEATHS FROM CHLOROFORM AND ETHER SINCE THE HYDERABAD COMMISSION.

The author has collected thirty-nine deaths from chloroform and four from ether. With neither anesthetic is the cause of death always the same, and both

heart and respiration should be watched. In the discussion the necessity of giving chloroform slowly was brought out.

DR. W. W. KEEN, of Philadelphia, read a paper on

#### LINEAR CRANIOTOMY FOR MICROCEPHALUS.

This operation is often mis-called *craniectomy*, which implies removal, whereas, in reality it is a long incision. This incision is carried from the frontal eminence parallel with the frontal suture across the lambdoidal suture, and a narrow piece of skull removed. This operation is as successful as making two incisions, and less dangerous.

DR. JOHN A. WYETH, of New York, read a paper on

#### SUPRAPUBIC CYSTOTOMY.

The abdominal wound is treated by the open method. The bladder is closed only when it is perfectly healthy, otherwise the wound is left to granulate. This is the safest rule to follow in suprapubic bladder operation. Twenty-three cases were reported without a death.

DR. W. R. TOWNSEND, of New York, read a paper on

#### SPRAINS OF THE ANKLE.

Flat-foot is not infrequently the result of improperly treated sprain of the ankle. The leg should be elevated, and strips of adhesive plaster carefully applied in different directions over the seat of injury, and a pressure bandage put over this, or in case of a more severe injury, a plaster-of-Paris bandage should be put on for a few days only. The patient may use the foot within reasonable limits after the apparatus is applied.

DR. ROBERT NEWMAN, of New York, read a paper on

#### PLATINUM NEEDLES FOR ELECTROLYSIS.

Platinum is by far the best material for needles, but is so easily bent that it is often difficult to manipulate. To overcome this difficulty, the author has made a steel needle with a groove, which is first put in, and the platinum needle inserted along the groove. The steel needle is then withdrawn.

### Recent Literature.

*The Prolivity of Women to Cancerous Diseases.* By HERBERT SNOW, M.D. (London). London: J. & A. Churchill. 1891.

This book is the substance of a lecture given by the author at the Cancer Hospital in London. The points which he makes are in brief as follows: That women are more prone to cancer than men no one can doubt. The two organs which give this greater predominance in women are the uterus and the breast. He considers that there is a special liability to cancer in parts "where the cell elements subsist in unstable equilibrium, that is, are prone to frequent modifications and changes in individual growth or relative arrangement, and are very intimately controlled by the nervous system." Conditions which are typically found in the uterus, and also in the breast.

As exciting causes, traumatism accounts for a few cases; the majority, however, are due to various depressing neurotic conditions, particularly mental dis-

tress. These neurotic conditions he associates with the invalidism so notoriously characteristic of civilized women, and as *general* causes of such invalidism he cites three: constipation, over-pressure at school, and abuse of neurotics, especially tea. The one grand *local* cause of the chronic ill health of women the author finds in the corset, and he sums up the whole lecture in this piece of practical advice: "Aim at removing the causes which among us so conspicuously impede the female sexual organs in the due performance of their allotted functions. You will then succeed in hugely diminishing the prevalence, not only of cancer, but of every other specially female complaint, and will go far to remove that reproach of chronic invalidism under which the fairer half of our community now so needlessly rests."

While we do not agree in toto with the conclusions of the author, notably in the opinion that mental distress causes cancer, and that the corset is the one important factor in the production of female diseases, yet there is much that is suggestive. The book includes also a short paper in which the author proves very conclusively from statistics the fallacy of the opinion that cancer is hereditary.

*Treatment of Hemorrhoids and Other Non-malignant Rectal Diseases.* By W. P. AGNEW, M.D. San Francisco, Cal.: R. R. Patterson, Printer. 1890.

In this little work the author has endeavored to place before his reader an intelligent idea of the non-operative treatment of the above diseases. He has gone at full length into details in the treatment of these respective affections, and while the work is evidently the outcome of personal experience, it can hardly be considered a broad and safe guide to the scientific treatment of these conditions. Much that appears in the work would appeal to the mind of the laity, but would hardly be accepted by surgeons. Its construction is crude; practical points appear scattered throughout the book.

*The Principles and Practice of Surgery; Being a Treatise on Surgical Diseases and Injuries.* By D. HAYES AGNEW, M.D., LL.D., Professor of Surgery in the Medical Department of the University of Pennsylvania. Profusely illustrated. Second edition, thoroughly revised, with additions; in three volumes. Philadelphia: J. B. Lippincott Company. London: 10 Henrietta St., Covent Garden. 1889.

This work presents in a striking manner the life interest of Dr. Agnew, and shows clearly his energy and industry. One cannot fail to admire the personal imprint of the author's experience which appears so frequently in the work.

There are few men whose experience has been more sought after than the author's, and while a great deal of the newer work which has come forward in surgery is not presented, it may be truly said that in these three volumes we have a trusty and reliable guide to the surgeon or physician.

*A Text-Book of Medical Jurisprudence and Toxicology.* By JOHN J. REESE, M.D. Third edition. Philadelphia: P. Blakiston, Son & Co. 1891.

The work, of which the volume now under notice represents the third edition, appeared originally in 1881, and the fact that in this brief interval two editions have been disposed of by the publishers is alike complimentary to the author, and a demonstration that

his text-book satisfies a growing interest in legal medicine. The changes introduced in the text are uniformly in the nature of improvements and are a recognition of the progress which medical jurisprudence is making, in common with other departments of medicine. Our comment on the second edition of this valuable work is true of this third edition also: "Within the limits deliberately set by the author, that he would make a text-book and not a treatise, this volume fulfills its purpose as a concise and comprehensive manual of medical jurisprudence, a work in which one may obtain an accurate knowledge of the essentials of legal medicine."

*Le Courant Continu en Gynécologie.* Publie par le Dr. GEORGES GAUTIER. Paris: A. Maloine, Éditeur. 1890.

This is a reprint of a few of the more important papers on the use of the continuous current in gynecology, which were read at the International Medical Congress at Berlin in 1890.

The first and most interesting is by Apostoli, followed by one by the publisher, Dr. Gautier, and by four others: by Bröse, of Berlin; MacGuinness, of New York; Meyer, of Copenhagen; and La Torre, of Rome. They have already appeared in abstract, but will be more valuable in this complete form.

*Practical Treatise on Electricity in Gynecology.* By E. H. GRANDIN and J. H. GUNNING. New York: Wm. Wood & Co. 1891.

That electricity as a curative agent in diseases of women is attracting increased attention everywhere is evidenced by the fact that this is the third book on the subject that we have been called upon to review in a little more than a year.

Examination shows this one to be in some ways an improvement upon its predecessors. The two respects in which this is most evident are, first, in the clearness and simplicity with which the general consideration and description of apparatus are given; and second, the conservative view of the value of this agent which is taken. As the authors say in their preface, "The agent is considered not from the standpoint of a specific, but as a valuable adjuvant to routine therapeutic methods."

Its mode of application in the various diseases peculiar to women is fully described, and its limitations noted. In spite of the favorable reports of its effects in a large number of the more common affections, we cannot but feel that equally good results can be obtained by other methods, which take less time in their application and require less expensive apparatus than electricity.

If, however, one wishes to try this agent, he cannot do better than follow the principles laid down in this book, which, in our opinion, is the best one on the subject.

THE EYES OF WILD ANIMALS. — Maintaining that short-sightedness, or myopia, is a product of civilization, M. Motais, of Algiers, cites his ophthalmoscopic experiments with the eyes of tigers, lions, and other wild beasts. Those which are captured after they are six or eight months old and remain hypermetropic, while those that are captured earlier, or are born in captivity, are myopic.

THE BOSTON

**Medical and Surgical Journal.**

THURSDAY, MAY 28, 1891.

*A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.***SUBSCRIPTION TERMS:** \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.*All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.**All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.**Remittances should be made by money-order, draft or registered letter, payable to*DANRELL & UPHAM,  
283 WASHINGTON STREET, BOSTON, MASS.**A FOUR-YEARS' COURSE AT THE HARVARD MEDICAL SCHOOL.**

A VERY important step has recently been taken by the faculty of the Harvard Medical School in increasing the course of study from three years to four, as announced in the JOURNAL of last week. The proposed change will not go into operation until September, 1892, and will not affect students now in the school nor those who may enter during 1891.

The details of the new course are not yet arranged, certainly not yet made public; but in general it may be said that the entrance examination will remain the same as at present, and the course itself will comprise four years of nine months' study each. Certain essentials of a medical education which the student is expected to acquire, but on which no examination is at present required, will be put upon the list of requirements for graduation.

Undoubtedly the requirement of an additional year will occasion a falling off in the number of students. How great the diminution will be cannot be determined, as there are no data available on which to found even a conjecture. The four-years' optional course which has been in operation for several years, has been taken by a slowly increasing, but still comparatively small, number of students. It has never been very popular, and does not represent the number of students who are willing to devote the time necessary to obtain the best education available.

As is the case in other institutions of learning, students who possess sufficient knowledge to pass the regular examinations in the studies of the first years will be able to enter advanced classes. It is possible that college students who know early enough that they are to study medicine may be able to so shape their collegiate course as to take advanced standing in the medical school, and thus still complete the two courses for the A.B. and M.D. degrees in seven years; but no arrangement between the two faculties to facilitate such an economy of time has been made.

The decision to require four full years instead of

three has been arrived at by the Harvard faculty, after long consideration. As to the desirability of such a course, there has been no difference of opinion, we believe; as to the advisability of the change, there has evidently been some doubt. The school must inevitably face a diminution in the number of its scholars and a corresponding decrease in income. In voting to carry out the new course the professors of the school run the risk of a very material decrease in their already meagre salaries, a risk which they willingly take. The school is at present in a very flourishing condition; and the faculty are evidently influenced by other motives than the desire for material prosperity in making the proposed addition to the time limit. The expected deficit has been in part provided for by a subscription from friends of medical education.

A similar move towards higher medical education has been taken by the Medical Faculty of the University of Pennsylvania. At a meeting of the Board of Trustees of that University, held May 21st, Dr. Pepper, the Provost, made an offer of \$50,000 towards an endowment fund of \$250,000, and of \$1,000 annually towards a guarantee fund of \$20,000 annually, for five years, conditioned upon the establishment of an obligatory graded four-year course of medical study. The Medical Faculty pledged themselves to carry out this proposal, and to enter upon the four-year course in September, 1893, and subscribed \$10,000 annually for five years to the endowment fund. The Board of Trustees approved the proposed change, but postponed their assent until the success of both funds had been demonstrated.

There is reason to believe that a similar change is seriously contemplated in New York. A nearly simultaneous change in New York, Boston and Philadelphia would compel other schools to follow their example.

This movement ought to meet with the general approval and co-operation of all who have the best interests of the medical profession at heart. It means an education equal to that obtained in other countries, and the acknowledgment of American degrees by English and Continental authorities. It is a question whether it may not result in a change of character in the American doctor; whether the number of graduates in arts who subsequently study medicine may not grow proportionately less in number, and the scholarly element be replaced by a more distinctly scientific one. But whatever change of that sort may take place, the time involved is much better proportioned to the importance of the student's life work, and the medical graduate of coming years ought to be a distinct improvement on his predecessors.

**PHYSIOLOGICAL ALBUMINURIA.**

The appearance last year of a second edition of Senator's treatise on "Albuminuria," and the publication the present year of a French and English translation of the same, taken in connection with a rather

spirited controversy concerning some of Senator's positions in late numbers of *La Médecine Moderne*, in which Senator has had to defend himself against the vigorous assaults of Lecorché and Talamon, render the moment opportune for some reflections upon physiological albuminuria. We shall, in the present article, consider the subject from Senator's standpoint.

(1) The fact of the occasional occurrence of albumen in the urine of healthy persons is not now a matter of dispute. Senator, in summing up the statistics of four competent observers, estimates "that out of 100 vigorous men, in good health, and in particular soldiers, there have been 41 in whom, without the intervention of any extraordinary factor, albuminuria has been found."

(2) The albuminuria under consideration is only "the physiological exaggeration of a normal process." It is asserted that there are always traces of albumen in normal urine, as can be determined by special tests, but under certain conditions the quantity of albumen increases, and quite a perceptible cloudiness manifests itself under the agency of the ordinary tests, heat and nitric acid. Physiological albuminuria belongs to the same category as physiological glycosuria, physiological oxaluria, etc.

(3) The factors which cause the albuminuria to vary are as follows: (a) muscular work, (b) digestion, (c) cold bathing, (d) intellectual fatigue and violent emotions, (e) menstruation.

(a) Extremely arduous exercise engenders a transient albuminuria, or aggravates an albuminuria already existing.

(b) Digestion has a similar effect. Grainger Stewart's observations show that of the daily repasts the breakfast is most likely to render a person albuminuric. Senator's observations also show the influence of a full meal, and especially breakfast, on the production of temporary albuminuria.

(c) The influence of cold baths has been shown in the case of healthy soldiers by the observations of Châteaubourg, G. Johnson and Grainger Stewart.

(d) Transient albuminuria has been known to follow severe mental exertion and violent emotion.

(e) The influence of menstruation has been affirmed, but is not so clear.

Albuminuria arising from such causes has been called by Pavy "cyclical"; it comes and goes with a certain regularity. It is worthy of remark that all the pathological forms behave in the same way, and present aggravations after exercise, meals, excitations, emotions, etc.

When does albuminuria cease to be physiological? There can be no absolute answer to this question. Of course, albuminuria can be regarded as physiological only when existing in persons who are in all respects healthy, and who, apart from this albuminuria, present nothing abnormal. As far as the urine is concerned, the existence of only a minimum quantity of albumen — just enough to give a faint cloudiness to the ordinary reagents — is compatible with the physiological

condition. "Every pronounced case of albuminuria should, from the very first, be regarded as morbid." As for the limit, beyond which the albuminuria ceases to be normal, Senator, with others, fixes this at about 0.4 per cent. Moreover, the urine, when recently voided, should be normal as to volume, aspect, density and composition, and must be exempt from figured elements. Finally, physiological albuminuria is ordinarily, if not always, of short duration, being most marked in the morning and disappearing later in the day.

The albuminuria of advanced life must, by reason of the frequency of morbid degenerations in the aged, generally be regarded as pathological.

As for the mechanism of the elimination of albumen by the urine, Senator is disposed to regard this as the result of simple filtration from the capillary tufts into the capsules of Bowman. He rejects the theory of Heidenhain (so generally accepted at the present day), which makes the urine a secretion, and attributes to the epithelium of the capsules the rôle of removing water and salts, while the epithelium of the canaliculi separates the urea and other solids; according to him, the urine is both a transudation and a secretion. The watery part transudes through Bowman's capsules in accordance with physical laws; the solid elements are removed from the blood by the vital selective action of the rod-containing epithelia. The urine, being thus partly a transudation, would naturally contain albumen, like other transudations (for instance, the cerebrospinal fluid, the aqueous humor). Senator does not deny this, and declares that the proper chemical tests will always reveal the presence of albumen in minimum quantity. The proportion of albumen will generally be small, as in all normal transudations, for albumen is a colloid and dialyzes feebly. Physiological albuminuria is but the result of an augmentation of the albumen, which in normal urine filters with the water of the blood into the capsules of Bowman.

Senator insists that the two liquids, which by their reunion constitute the urine (transudation and secretion), do not obey the same laws of function, and that they are not always modified in the same direction. As for the *transudation*, the measure is given chiefly by the conditions of the circulation, that is, the pressure and rapidity of the latter, then by the composition of the blood. As for the *secretory function*, its activity is dependent on certain *specific irritations*, acting directly on the epithelial cells or by the intermediation of the nervous system.

As for the physical conditions which favor albuminuria, many of the observations respecting the influence of blood pressure, swiftness of the current, etc., have thus far been contradictory, and give but little light on the subject. No very positive conclusions can be drawn from the effects of ligature in animals of the renal artery or vein, cutting the renal nerves, etc. There is as yet no evidence that modifications of the blood pressure play any considerable part in the production of albuminuria; Senator, however, is disposed

to make more account of such modifications in the causation of physiological albuminuria than of that *epithelial alteration* to which Lecorché and Talamon ascribe the principal rôle. In our judgment, the weakest part of Senator's work is the short chapter where he attempts to explain physiological albuminuria, or define the boundaries which separate the physiological kind from the truly pathological. Naturally when we approach the pathology of febrile albuminuria and the albuminuria of nephritis, the difficulties are not so great, for high febrile heat, as well as inflammation, increases the permeability of the renal filter, and permits a transudation rich in albumen. This is a fact which can be demonstrated.

Senator has probably left himself open to the charge of ascribing too inconsiderable a rôle to the epithelium of the glomeruli, whose alteration, according to Lecorché and Talamon, is the principal factor in albuminuria. In fact, to these writers, persistent albuminuria is always glomerulitis. It is impossible to read the work of these authorities without being impressed by the wealth of fact and of argument by which they aim to show that under all circumstances physiological as well as pathological albuminuria indicates some lesion, however trifling and transient, of the glomerular filtering membrane. In all the inflammatory and degenerative diseases of the kidney this epithelial disease is demonstrable. Unfortunately, however, it is rather by deductive reasoning than by direct evidence (which it is, of course, impossible to obtain) that the conclusion is reached that the slighter, evanescent forms of albuminuria are in any sense morbid.

It seems to us that the only practical outcome of this still unsettled dispute is the acquisition of the facts:

(1) That we do not yet precisely know the mechanism of the urinary secretion. Heidenhain's theory seems very plausible, and is, perhaps, the best *working* theory, but we do not really *know* that the epithelium of the glomeruli secretes water and salts and keeps back albumen.

(2) That it is quite possible for slight, temporary forms of albuminuria to exist within the limits of what may be regarded as good health. Whether in such cases the epithelium of the glomeruli is temporarily *diseased* or not, we do not know, and it is waste of time to discuss the question.

(3) That for the presence of albumen in the urine to be of real prognostic value in any case (as in examination for life insurance), the medical expert must not be content with merely one examination of the urine, but must make several tests, under different circumstances, and at different hours of the day.

#### MEDICAL NOTES.

BRITISH MEDICAL ASSOCIATION. — The fifty-ninth annual meeting will be held at Bournemouth, July 28–31, 1891. President, Willoughby Francis Wade, M.B., F.R.C.P.; President-elect, John Roberts Thom-

son, M.D., F.R.C.P. Addresses will be delivered as follows: in Medicine by T. Lauder Brunton, M.D., F.R.S.; in Surgery by John Chiene, M.D., F.R.C.S.; in Public Medicine by Edward Cox Seaton, M.D. The scientific business of the meeting will be conducted in nine Sections.

REQUEST FOR INFORMATION CONCERNING SMALL-POX AND VACCINATION. — The Marine-Hospital Bureau has received a letter from the British Legation in Washington, requesting authentic information regarding the occurrence of epidemic small-pox in the United States, and also regarding "any case of injury alleged to be due to vaccination, that may excite public attention." This information is requested in behalf of the English Royal Commission on Vaccination. Those who may be sufficiently interested to contribute to the information desired are informed that short descriptive articles upon any local epidemic of small-pox, and any properly authenticated account of injury alleged to be due to vaccination, if sent to the Marine-Hospital Bureau, will be forwarded, through proper channels, to the British Legation, and due acknowledgment will be made therefor.

AN ITALIAN PHARMACOPEIA is about to be published. This will be the first national formulary, those hitherto in use having been of the most varied description, consisting largely of more or less correct translations of French formularies, and having no general or official recognition.

A BOUNTY ON BABIES. — The "depopulation" of France and the means of checking the progress of the evil are subjects that have for some time engaged the attention of the Académie de Médecine, but the deliberations of that body have not yet led to the discovery of an effectual remedy. In the meantime M. Tarnier, the President of the Académie, has offered a bounty of one hundred francs to every married couple in his native commune who shall enrich the French Republic with an additional citizen during the year 1892.

OUTBREAK OF RABIES. — An outbreak of rabies commenced about two months ago in County Wexford, Ireland. The authorities have adopted a resolution requesting the Lord-Lieutenant to issue a proclamation, embracing the whole of Ireland, to restrain dogs either by muzzle or confinement for the length of time necessary to effectually stamp out the disease.

THE INGREDIENTS OF PRESCRIPTIONS. — A correspondent of the *Pharmaceutical Era* has tabulated 2,000 prescriptions, consecutively received by an apothecary, and written by 155 different physicians. The 2,000 prescriptions contained 5,012 ingredients, of which 4,220 were official, that is, pharmacopœial, 161 from the "National Formulary," 376 proprietary and 255 unofficial substances. Of the prescriptions 1,307 were entirely composed of official ingredients. A plea is made that physicians should become better acquainted with the "National Formulary," in order to discourage proprietary combinations.

**THE OWNERSHIP OF PRESCRIPTIONS.**—The question as to who is the legal owner of a prescription has been discussed recently in English medical journals and in the pharmaceutical papers in this country. Different opinions have been advanced, one that it should belong to the physician on the same principle that a check is returned to the drawer from a bank; a second that it belongs to the patient, since he has paid for it; and a third that it should be the property of the apothecary, as being a note addressed to him, and also as evidence in case of question of proper compounding. A correspondent of an English paper says that in Prussia—though no special law on the subject exists—it is invariably considered the property of the patient. A prescription can be made up again and again, as often as the patient wishes, unless in contain dangerous substances, in which case the prescription must be marked "*ad libitum*" or "*reiteretur*" by the physician. There is no limit to the time within which a prescription must be presented.

**MEDICAL ORTHOGRAPHY.**—The following are a few of the many ways in which the word physician was spelt on different medical affidavits, passing through the hands of a Washington attorney, in which the affiants stated their occupation under oath: fazi-tion; fician; fescion; phisishun; physian; physition; physican; fosition; physicean; facetion; phasician; physiceun; fosishun; phisornton; phshun; fasian; physiciation; physicaean; physycun; phicision; phizician; fizion; focicent; phician; phycion; physicaean; phycian; fursision; phasisun; phesition; fezetun.

Among the answers from candidates for license to practice medicine in Minnesota at a recent examination, the following words appeared: colatrial, ariate, higinac, utris, utrin dush, serious fluid, playsenta, bactria, puss, bouls, vetbra, serberlium, parylis of the svinctar, likar sauger.

**A THREATENED STRIKE OF MEDICAL MEN IN SCOTLAND.**—A largely attended meeting of medical men, was held in Edinburgh, a few months ago, to debate the grievances of over-work and under-pay so long felt and hitherto so patiently borne. Mungo Park, who had experienced both courses of life, is said to have given the preference as regards hardship to a discoverer in Africa than to wandering by night and day the wilds of his native land in the capacity of a country medical practitioner. One gentleman said he had been over fifty years in the profession. His working day was nearer twenty-four hours than eight or ten, during which he was either actively engaged in the service of the public, or in anxiety that he might be called forth to mount his horse, perhaps at midnight, and transverse in darkness paths dangerous in daylight. He received annually forty pounds from the parochial board, for which he was bound to give his skill and services to any poor person in his district. What was the result of half a century of such work? "He had earned a living, no doubt, but he had not saved one penny!" Another practitioner, from a colliery dis-

trict, said that he received a penny and a half a week from some hundreds of miners, and for this he was expected to be always ready. The other speakers bore similar testimony. A strike was advocated very plainly by some, but by others was discountenanced. In the end a committee was appointed to consider the grievances of Scotch medical men, and to report on the remedies.

#### BOSTON AND NEW ENGLAND.

**MASSACHUSETTS GENERAL HOSPITAL.**—A house, to be used as the private residence of the Superintendent, is to be built on the corner of Blossom and Allen Streets.

**MASSACHUSETTS MEDICAL SOCIETY.**—The annual meeting, of which a programme appears in another column, will be held in Boston, June 9th and 10th. The Fellows of the Society are invited to visit the different hospitals, as usual, on Tuesday, at 10 A. M. There will be an exhibit in the Mechanics Building of surgical apparatus, including a special exhibit of orthopedic appliances from the Children's Hospital, legitimate pharmaceutical preparations, sanitary and other appliances pertaining to medical science.

**HOSPITAL IN NATICK.**—A will which leaves the town of Natick \$150,000 for a hospital has been sustained in the lower court, but will be appealed to the Supreme Court.

**INFLUENZA.**—In spite of the numerous cases of epidemic influenza which were reported a few weeks ago, the fact that the epidemic in Massachusetts has not been very fatal is shown by the death-rate of the State which for the three weeks ending May 9th was 21.68, 19.34 and 19.45 respectively. In Connecticut in April there were 1,260 deaths reported, which is 192 more than the average for April for the previous five years. The death-rate for the large towns was 19.8, for the small towns 21, for the whole State 20.3.

#### NEW YORK.

**CHILDREN'S WARD AT THE GOUVERNEUR HOSPITAL.**—Through the efforts of Dr. H. M. Silver, the visiting surgeon, a new ward for children has been secured at the Gouverneur Hospital, one of the small down-town city hospitals, and during the past week it was opened for the reception of patients. It is situated on the top-floor, commanding a fine view of the East River and of Brooklyn, and is intended for surgical cases and cases of acute, non-contagious diseases. Nine of the ten beds were occupied on the day of the opening.

**IMAGINARY HYDROPHOBIA.**—A German, twenty-seven years of age, died May 20th of what was probably imaginary hydrophobia. About a month ago he was bitten by a dog which did not at the time show, nor has since exhibited any signs of rabies, but by the foolish representations of friends he was apparently frightened into the belief that he was getting hydro-

phobia, and when this idea once got possession of him the looked-for symptoms readily presented themselves, and in a few days the fatal termination was reached. The physician who attended the patient placed the case in the coroner's hands, and an autopsy was made by Dr. Jenkins, the coroner's deputy, who was unable to arrive at any definite conclusion as to the existence of hydrophobia, until a microscopical examination of the spinal cord should have been made.

**MATRONS AT POLICE STATIONS.**—The first competitive examination of applicants for the position of matron at the various police station-houses, required by a recent act of legislature, was held May 20th in the rooms of the Civil Service Board at Cooper Union; Dr. H. F. Vosburgh acting as medical examiner. The police matrons must be between thirty and forty-five years of age, and, among their other requirements, must be able to act intelligently in cases of child-birth, intoxication, surgical injuries, etc., among the women brought to the station-houses.

### Miscellany.

#### HIGHER MEDICAL EDUCATION.

A CIRCULAR has recently been issued by the University of Pennsylvania, announcing the probable establishment of a compulsory four-years' medical course at that University, under the conditions mentioned in another column of this issue. This circular is especially interesting, coming as it does shortly after similar action by the faculty of Harvard Medical School; and we therefore quote from it at length:

"Higher medical education is the true interest of the public and of the medical profession. Nothing concerns more directly every individual member of the community than that our medical men shall receive a thorough and practical education. In all civilized countries except America from five to seven years are devoted to this purpose, although their students enter the medical schools with better preliminary education than the vast majority of ours enjoy. In each European country there are only a few schools privileged to confer medical degrees, so that it is easy to maintain a high standard. But in this country there are hundreds of medical schools intrusted with this great power and high responsibility. Keen competition keeps down the standard. Until a few years ago it was the rule that only two years' study was required. Conscience revolted at this shocking laxity, and a few schools advanced their standard and established a three-year obligatory graded course of medical study. It was done in the face of much opposition, but it was done successfully, and to-day no medical school has any standing which has not adopted the three-year course. It was known to all who had studied the subject that this advance was but the first step. The number of subjects to be taught has increased; the methods of medical instruction have grown more exacting and thorough; above all it is felt that no student should receive a degree which empowers him to enter on the most responsible work of practising medicine unless

he has had ample bedside instruction in every branch of his profession. It is simply impossible to do this in a three-years' course. Students are overworked in the attempt. The more complete the facilities possessed by any school the more evident has it become that one more advance must be made to enable the student to profit by his opportunities and to become a well-trained physician. The old cry is still raised that there were eminent doctors in former days who had studied only two years, and that those who graduate now with three years' training succeed well in their profession. But every one who advances this argument knows how specious and hollow it is. It is universally admitted by the public and the medical profession alike that it is impossible to-day to give a thorough medical education in less than four full years of actual work in lecture-room, laboratory, and hospital. . . .

"The school which puts into operation a full four-year graded course of medical study must be ready to meet increased outlay and lessened income from students' fees for some years at least. But what is resigned in mere pecuniary profit will be many times over compensated by the lasting influence for good exerted."

#### THE EXTREMES OF TEMPERATURE BORNE BY THE LEUCOCYTES OF HUMAN BLOOD.

MAUREL<sup>1</sup> publishes some very interesting researches upon this subject. He describes the different forms of leucocytes found in the blood, as illustrating somewhat their life-history there. He then details the results of his experiments in subjecting blood to different degrees of temperature, watching meanwhile the effect upon the power of motion and upon the life of the white corpuscles. A degree of cold below 16° C. could only be borne by them for a short time, and 14° C. was immediately fatal. On the other hand, a temperature above 44° C. rapidly threatened their life, while one of 47° C., even for a few minutes, suffices to kill them.

From a clinical standpoint these experiments show that the greatest degree of activity of human leucocytes is witnessed at the temperature of the blood in a normal state, or during a febrile state of slight intensity. As is well known, the axillary temperature is about two degrees less than that of the blood in the interior of the body. It is evident, therefore, that in very high fever, with an axillary temperature of 41° C., or, exceptionally, of 42° C., a point is being approached at which the life of the leucocytes is seriously threatened.

#### INTERLOBAR PLEURISY.

PROFESSOR POTAIN contributes a paper to the *Union Médicale*, No. 27, 1891, dealing with the subject of interlobar pleuritic effusions.<sup>2</sup> A typical case is recorded where pus is periodically evacuated through the bronchi, and in which there are evident signs of fluid effusion in front of the upper lobe of the left lung, but not in the general pleural cavity, the fluid being probably localized by firm adhesions. The diagnosis of such cases is always difficult, and a localized

<sup>1</sup> *Comptes rend. d. Soc. d. Biol.*, 1890, ii., 528, and *Ann. Jour. Md. Sciences*.

<sup>2</sup> *British Medical Journal*, April 14th.

collection of fluid may frequently be mistaken for a solid mass unless due precautions are taken. They commonly occur as interlobar effusions or as effusions between the lung and the diaphragm. In either case they are almost always purulent. The occurrence of frequent rigors and a dry cough, if not due to congestion or accompanied by signs of a general pleurisy, should always suggest the possibility of interlobar effusion. Physical signs may not at first be present, but show themselves as the fluid approaches the surface. It is usually evacuated through the bronchi, setting up a certain amount of irritative bronchitis in the process. The opening into the lung is usually small and irregular, and it is rare for air to escape from the lung into the abscess cavity. In cases where such escape does take place it generally happens that putrefactive changes are set up in the fluid which remains behind, and this necessitates an operation to evacuate and disinfect the cavity. In cases such as the one related, where there is no evidence of change taking place in the put up fluid, no operative measures are proposed. Unlike a general empyema, the interlobar form shows a marked tendency to spontaneous cure.

#### EFFECT OF QUININE ON THE HEALING OF WOUNDS.

DR. SOKOLOFF has published some interesting observations on the effect of quinine administered to a wounded animal on the granulation and cicatrization of the wound.<sup>1</sup> The experiments were conducted on rabbits. The fur was shaved from a portion of the paw, and an incision made through the skin and into the muscular tissue, the external wound being then sewn up and the whole dressed antiseptically. Subsequently microscopic observations were made on sections including the wound. Twenty-four rabbits which were experimented on in this way were treated with hydrochlorate of quinine, half a grain of which was given per diem for each kilogramme of body weight. A similar number of control rabbits were operated upon in precisely the same manner, but were not given quinine. The author gives a detailed description of the microscopic appearances observed each day for eight days in the two sets of cases. The effusion of blood was much the same in both, but there was a marked difference in the condition of the muscular tissue. In the control animals this lost its striped character, the portions in the immediate vicinity of the wound presenting the appearance of an amorphous homogeneous substance containing here and there a few muscular fibres or breaking up into separate pieces as in coagulation necrosis. Besides this, the muscular tissue gradually disappeared, leaving sheaths of sarcolemma either empty or filled with cells. In contrast to this state of things sections taken from the animals treated with quinine presented little or no sign of muscular degeneration, the fibres preserving their proper structure. With regard to the cellular elements in the control animals, two forms were found in the neighborhood of the wound—a large number of multinuclear leucocytes, and a much smaller number of large round or oval cells with a single large nucleus. During this period the nuclei presented various karyokinetic figures. In animals treated with quinine there was no multi-

nuclear cells, all being oval, with a single nucleus and smaller than the corresponding cells in the control animals. The cells were, moreover, more numerous than in the control observations. In the quinine-treated animals the karyokinetic process commenced and finished earlier than in the others, the chromatin filaments being also less numerous but thicker. Altogether there was less inflammation with quinine than without; in short, without quinine there was Zenker's degeneration, with quinine, none.

#### MEDICAL EXPERT TESTIMONY.

REESE<sup>1</sup> takes the opportunity afforded by a recent trial to call attention to the very unsatisfactory methods of medical expert testimony which prevail in this country. At this trial four highly respectable practitioners, one with very large experience in such matters, all testified to certain appearances presented by the wounds upon the dead woman's neck, but not agreeing among themselves in relation to certain other appearances. Among the points specially noticed and testified to by these gentlemen, were the situation, the nature, the direction, and the extent of these wounds. They all coincided in the opinion that certain of the injuries—those which penetrated to the vertebrae—were inflicted by a stabbing, or *thrusting*, of the lethal weapon, whilst the others were undoubtedly of the nature of incised wounds. And, further than this, two of those witnesses expressed their opinion that the right carotid artery had been cut, or partially severed, by a wound inflicted on the right side of the neck, which had extended around to the front of the throat.

These are points of purely anatomical significance, about which one might suppose there could be no possibility of doubt or opinion. But what a remarkable spectacle was presented to the court and assembled crowd of on-lookers when the defence produced the very neck of the dead woman, which had been dissected from the dead body by their experts, and which now, after nearly four months' interval, they were permitted to offer in open court for the inspection and personal handling of each jurymen!

It appears that the body was secretly exhumed by the defence some weeks after burial, and without the knowledge or authority of the court or the prosecuting attorney; and that during the interval their experts made their several investigations, and now, on the witness stand, these experts, in number and professional standing and ability the equals of their opponents—three of them well-known professors in our medical schools—came forward and declared that the right carotid artery was *not cut at all*, but was uninjured, and that "the wound at the back of the neck" was only superficial, and did *not* penetrate to the bone.

The author asks, "What impression is such an exhibition of so-called 'expert testimony' calculated to produce on the minds of the court and jury, and of the legal profession generally, to say nothing of the popular sentiment? Is it not likely to very much weaken the respect and confidence in all such testimony, and to bring it into disfavor, much to the detriment of justice? But, in passing we may remark, What impression would the average jurymen gain by looking at, and even *handling*, an anatomical specimen nearly four months old, taken out of a jar of alcohol before his

<sup>1</sup> *Lancet*, May 25th.

<sup>1</sup> *Medical News*, May 23d.

eyes? Would he not be very apt to both see and feel pretty much as the expert should describe and manipulate the parts before him?"

### OBITUARY. ALFRED HOSMER, M.D.

DR. ALFRED HOSMER was born at Newton Upper Falls, September 11, 1832. He attended school at Newton until his ninth year, when his mother removed to Walpole, N. H., where he found meagre opportunities for obtaining an education. He succeeded, however, in entering Harvard, and graduated with honor in the class of 1853. He immediately entered the Harvard Medical School, and graduated in 1856. He served as house-officer at the Massachusetts General Hospital. He spent nearly a year in Paris. He began the practice of medicine at Watertown in 1857.

In June, 1860, he married Helen Augusta, daughter of the late Josiah Stickney.

Dr. Hosmer became a Fellow of the Massachusetts Medical Society in 1856; has repeatedly been a member of its council; was its anniversary chairman in 1877, and its president in 1882. He was president of the Obstetrical Society of Boston; was president of the Middlesex South District Medical Society; was medical examiner for the Seventh District of Middlesex County; was the first president of the Medico-Legal Society; was for many years post-surgeon at the United States Arsenal at Watertown.

In 1879 he was made Fellow of the American Academy of Arts and Sciences; and in 1881 he was a member of the State Board of Health, Lunacy and Charity.

He contributed several papers to the *Boston Medical and Surgical Journal*, among which was "A Peculiar Condition of the Cervix Uteri which is found in Certain Cases of Dysstocia."

He was very active outside of his profession. He was a member of the School Committee for six years; was a member of the Board of Trustees of the Free Public Library for ten years; was a trustee of the Watertown Savings Bank fourteen years, and its president six years. He was president of the Watertown Historical Society at the time of his death.

December 29, 1888, while in seeming robust health, he was stricken down by a cerebral hemorrhage. He partly recovered, but never fully regained his power of speech. On the 14th of May, 1891, after a week's illness, he suddenly died of, as disclosed by the autopsy, rupture of the thoracic aorta.

Dr. Hosmer, more than most physicians, occupied a place of unusual importance and influence in the community in which he lived. Much might be said of him as a faithful physician and an ardent Christian, but such post-mortem praise would have been peculiarly distasteful to him.

### PRESCRIPTIONS.

**GUAIACOL IN PHTHISIS.**—Picot<sup>1</sup> uses for subcutaneous injection in pulmonary tuberculosis a clear fluid, made by dissolving one centigramme of iodoform and five centigrammes of guaiacol in one cubic centimeter of sterilized olive oil and vaseline. This is the initial dose, and it is gradually increased to three cubic centimeters. The suprapubic fossæ are chosen for the injection.

Diamantherberger<sup>2</sup> uses the following injection:

R Guaiacol . . . . . 55 3 ss.  
Oil of sweet almonds }  
Hydrochlorate of cocaine . . . . . gr. v. M.

This is sterilized by heat. The amount used must be regulated by the reaction. The author commonly injects seven minims every second day for two weeks, and then increases the frequency and the amount.

**VEGETATIONS ON THE GENITALS.**—The *Médecine Moderne* gives the following:

R Acidi salicylici . . . . . gr. viij.  
Acidi acetici . . . . . 3 ij. M.

Apply to the warts with a camel's hair brush once or twice a day.

**AMENORRHEA.**—The *Medical News* quotes the following:

R Bichloride of mercury } . . . . . 55 gr. ij.  
Arsenite of sodium } . . . . . gr. iss.  
Sulphate of strychnine } . . . . . gr. xij.  
Carbonate of potassium } . . . . . 55 gr. xiv. M.  
Sulphate of iron }

Make into sixty pills, and give one pill after each meal.

**MOUTH WASH.**—To preserve the teeth the following wash is quoted from *La Médecine Moderne*:

R Acidi tannici . . . . . 3 i.  
Tinct. iodi . . . . . 55 3 ss.  
Tinct. myrrhæ } . . . . . gr. xij.  
Potassii iodidi . . . . . 3 i.  
Aqua rose . . . . . 3 iiss. M.  
Sig. One teaspoonful in a glass of warm water.

**QUININE.**—The following solution of quinine is said not to be disagreeably bitter:<sup>3</sup>

R Quinine sulphatis . . . . . gr. xv.  
Acid sulphurici dil. . . . . in xv.  
Ol. menth. pip. . . . . gttss. x.  
Sacharin (sat. sol.) . . . . . 3 v.  
Aqua ad. . . . . 3 vj. M.

<sup>3</sup> Tribune Med., March 4th.

### RECORD OF MORTALITY FOR THE WEEK ENDING SATURDAY, MAY 16, 1891.

Cities.	Estimated population for 1890.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from

Deaths reported 2,606; under five years of age 856; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrheal diseases, whooping-cough, erysipelas and fevers) 317.

<sup>1</sup> Semaine Médicale, March 4th.

<sup>2</sup> Gazette des Hôpitaux, March 10th.

acute lung diseases 463, consumption 318, diphtheria and croup 81, scarlet fever 65, diarrheal diseases 46, typhoid fever 36, measles 37, whooping-cough 36, cerebro-spinal meningitis 10, erysipelas 10, malarial fever 10.

From measles New York 22, Brooklyn 9, Philadelphia, Boston, Cincinnati, Washington, Charleston and Worcester 1 each. From typhoid fever Philadelphia 19, New York 5, Cincinnati 3, Brooklyn and Boston 2 each, Nashville, Lawrence, Chelsea, Clinton and Peabody 1 each. From whooping-cough New York 11, Philadelphia 6, Brooklyn 5, Boston and Washington 2 each. From cerebro-spinal meningitis New York 5, Philadelphia 4 and Washington 2 each, Brooklyn, Chelsea and Quincy 1 each. From erysipelas New York 3, Philadelphia, Boston and New Bedford 2 each, Brooklyn 1. From malarial fever New York, Philadelphia, Brooklyn, Nashville and Charleston 1 each.

In the twenty-eight greater towns of England and Wales with an estimated population of 10,010,426, for the week ending May 9th, the death-rate was 28.9. Deaths reported 5,555: acute diseases of the respiratory organs (London) 584, whooping-cough 189, measles 112, diarrhoea 43, fever 34, scarlet fever 32, diphtheria 31, small-pox (Liverpool) 1.

The death-rates ranged from 18.0 in Bristol to 59.3 in Sheffield, Birmingham 24.6, Bradford 40.0, Brighton 19.1, Hull 24.9, Leeds 48.3, Liverpool 31.1, London 24.0, Manchester 33.6, Newcastle-on-Tyne 31.6, Nottingham 24.2, Portsmouth 48.8, Sunderland 23.3.

In Edinburgh 22.9, Glasgow 29.4, Dublin 26.4.

### METEOROLOGICAL RECORD,

For the week ending May 16, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

### OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MAY 16, 1891, TO MAY 22, 1891.

Captain JOHN O. SKINNER, assistant surgeon, U. S. Army, Fort Davis, Tex., will proceed at once to Fort Clark, Tex., and report to the commanding officer for temporary duty. S. O. 41, Par. 3, Department of Texas, May 13, 1891.

By direction of the Secretary of War, Captain GEORGE McCRIEY, assistant surgeon, is relieved from duty at Fort Clark, Tex., and will report in person to the commanding officer, Fort McIntosh, Tex., for duty at that post. S. O. 114, Par. 4, A. G. O., May 19, 1891.

Captain WILLIAM E. BANISTER, assistant surgeon, is assigned to duty as medical officer with Troop B, Sixth Cavalry, while en route from Fort Myer, Va., to Fort Washakie, Wyo. On arrival of the troop at its destination, Captain Banister will return to his station at Washington Barracks. S. O. 104, Par. 3, Division Atlantic, May 20, 1891.

Leave of absence for one month, to commence on or about the 22d instant, is hereby granted to Captain MARSHALL W. WOOD, assistant surgeon, U. S. Army. S. O. 104, Par. 1, Division Atlantic, May 20, 1891.

By direction of the Secretary, the following assignments of newly appointed medical officers are ordered: First Lieutenant WILLIAM T. LITTLE, Jr., assistant surgeon, will report in person for duty to the commanding officer, Fort McPherson, Ga. For First Lieutenant BRUCE W. BROOKS, assistant surgeon, will report in person to the commanding officer, Fort Riley, Kan. For First Lieutenant MEREDITH W. HOLLAND, assistant surgeon, will proceed from Columbia City, Ind., to Jefferson Barracks, Mo., and report in person for duty to commanding officer of that post. For First Lieutenant GEORGE M. WELLS, assistant surgeon, will proceed from Peoli, Ind., to Columbus Barracks, O., and report in person for duty to the commanding officer of that post. S. O. 115, Par. 7, A. G. O., May 20, 1891.

### OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MAY 23, 1891.

GEO. A. BRIGHT, surgeon, detached from U. S. S. "Omaha," and granted three months' leave of absence.

V. C. B. MEANS, passed assistant surgeon, detached from U. S. S. "Omaha," and granted three months' leave of absence.

JAS. F. KEENEY, assistant surgeon, ordered for examination preliminary to promotion to passed assistant surgeon.

### SOCIETY NOTICES.

MASSACHUSETTS MEDICAL SOCIETY. — One Hundred and Tenth Anniversary. Meetings will be held in the Building of the Massachusetts Charitable Mechanics' Association, Huntington Avenue, Boston.

Tuesday, June 9, 1891. At 2 p. m., meetings of Sections. Section in Medicine: "Typhoid Fever," by Dr. W. H. Pierce; "The Bacillus of Typhoid Fever," by Dr. J. A. Jeffries; "Early Symptoms of Bright's Disease," by Dr. C. F. Widdington. Section in Surgery: "A Discussion of 'The Diagnosis and Treatment of Inflammations of the Appendix,' in which the following will take part, Drs. D. W. Cheever, John Housens, C. B. Porter, R. H. Fitz, W. F. Whitney, F. C. Shattuck, M. H. Richardson, J. W. Elliot, Alfred Worcester. Section in Obstetrics and Gynecology: "Moderately Contracted Pelvis," by Dr. R. W. Green; "Pessaries, their Use and Abuse," a discussion by Drs. C. M. Green, A. D. Sinclair, Edward Reynolds; "A Case of Triplets," by Dr. H. F. Vickery. At 8 p. m., the Shattuck Lecture, by Dr. Edward Cowles.

Wednesday, June 10th, at 9 a. m., business meeting. Papers: "Catber Fever," by Dr. Paul Thordike; "A Case of Nephrectomy," by Dr. Homer Gage; "A Case of Doubtful Psoriasis Abscess," by Dr. G. P. Twitchell; "How shall we Nurish in Acute Disease," by Dr. F. H. Williams. At 12 m., the Annual Discourse, by Dr. James B. Brewster. At 1 p. m., the Annual Dinner.

MAINE MEDICAL ASSOCIATION. — The thirty-ninth annual meeting will be held in Common Council Chamber, City Building, Portland, Me., Tuesday, Wednesday and Thursday, June 9, 10 and 11, 1891.

Members who desire to offer voluntary papers or reports of cases will please communicate, by letter or in person, with Dr. F. E. Small, 359 Congress St., or Dr. W. L. Dana, 600 Congress St., Portland, Maine Committee.

CLAS. D. SMITH, M.D., *Rec. Sec'y*, Portland.  
OSCAR W. STONE, M.D., *Cor. Sec'y*, Camden.  
SAMUEL B. HUNTER, M.D., *President*, Machias.

### DEATHS.

W. W. NASSAU, M.D., of Burlington, Iowa, Brigade Surgeon during the war, died, May 23d, aged fifty-nine.

T. H. BARTLETT, F.R.C.S., a well-known surgeon of Birmingham, Eng., died, April 29th, aged fifty-four.

### BOOKS AND PAMPHLETS RECEIVED.

International Clinics. A Quarterly of Clinical Lectures. April, 1891.

Getting Married and Keeping Married. By One who has done Both. New York. 1891.

First Annual Report of the Midwifery Dispensary, 312 Broome St., New York City. 1891.

VAGINAL HYSTERECTOMY FOR CANCER.<sup>1</sup>

REPORT OF TWENTY-ONE CASES, WITH NINETEEN RECOVERIES.

BY ERNEST W. CUSHING, M.D.

I DESIRE this evening to call your attention not so much to the technique of vaginal hysterectomy as to certain questions concerning the indications for this operation, the choice between total and partial extirpation of the uterus, the limitations within which total extirpation can and should be performed, and the results obtained. I will therefore consider these subjects in preference to those of the technique and various methods of the operation.

At the very outset we are met by the question of the diagnosis of cancer of the uterus, and of the differentiation of the various forms of the disease in this organ. Although, in many cases it is very easy to make a diagnosis simply by gross appearances which are sufficiently familiar to all physicians of experience, yet unfortunately when the affection has reached a stage where recognition is easy, it is often impossible to perform total extirpation, at least with any prospect of success; and our whole endeavor should be therefore to seek a definite diagnosis as early as possible. In the incipient stages of malignant disease total extirpation is easy, and not very dangerous, and it gives excellent prospects of permanent recovery; while if delayed too long, not only does the operation become far more formidable and difficult of accomplishment, but the recurrences are so frequent as to discredit all such operations.

It may be said, and by many it is claimed, that when cancer is discovered, and is limited to the cervix, a partial operation is all that is necessary, and great importance has been attached to the results of Schroeder and Hofmeier. The statistics published by the latter show that a far larger proportion of the cases operated on by Schroeder and himself by high amputation of the cancerous cervix remained free from relapse than was the case after those operations where the whole uterus was removed, from this fact many writers have jumped at the conclusion that a partial amputation is not only an easier and safer operation than total extirpation, but that it gives greater security against relapse. To understand this question properly, however, it is necessary to remember that the cases which Schroeder and Hofmeier treated by high amputation of the cervix were those of canceroid (epithelioma), in which the disease was entirely limited to the vaginal portion of cervix, and were therefore cases where the cancer was detected and removed at an early stage, and where it was of a nature tending to remain longer localized. On the other hand, the cases which Schroeder and Hofmeier operated on by total extirpation were those in which the cervix itself was involved, or where there was malignant disease of the body of the uterus; therefore it is very evident that in their hands the chances of relapse after total extirpation were much worse than after the high amputation of the cervix. In other words, they selected for the lighter operation cases of extremely limited and incipient disease, and in such there was, nevertheless, a very large per cent.

of recurrences, that is, over fifty per cent. It seems hardly doubtful that there would be fewer recurrences if the whole uterus were removed, even in cases where the disease is merely canceroid of the vaginal portion; and the consensus of opinion among Continental observers is now decidedly in favor of removing the whole organ whenever the diagnosis of malignant disease is clear. This view of the case I accept without hesitation. It should not be forgotten that the high amputation of the cervix is a difficult and somewhat dangerous operation, requiring a great deal of technical skill, and giving, even, in Schroeder's hands, a mortality of some eight per cent. In any case in which this operation can be performed the total removal of the uterus can be accomplished with little additional difficulty or danger, and affords greater security against hemorrhage as well as greater immunity from relapse.

The customary classification of malignant disease of the cervix as established by Schroeder is: (1) canceroid of the vaginal portion (corresponding to what is frequently known as epithelioma); (2) carcinomatous nodule of the cervix; (3) carcinoma of the mucous membrane of the cervix.

The twenty-one specimens here presented and the preparations exhibited under the microscope show these various forms; and it is to be remembered that it is only in the first and rarest of these three varieties that there is any claim of the efficiency of partial removal of the uterus. In both the other varieties, by common consent, total extirpation should be performed immediately on discovery of the disease, if, haply, it is not already too late to accomplish it.

It must not be forgotten that where carcinomatous disease of the cervix is present, even when the affection is limited to the vaginal portion, it is always possible that the malady also extends to the fundus; and for this reason alone, if for no other, total extirpation is indicated in all cases. I am aware that Hofmeier contends that there are but very few authenticated cases of simultaneous affection of the fundus and of the vaginal portion, except where the process is primary in the fundus and secondary in the vaginal portion.

Although, however, this view may be maintained academically and as a matter of rigid microscopical diagnosis, rejecting all cases where the description of the microscopical preparation is not entirely satisfactory, yet practically it is certainly possible in any given case of malignant disease of the cervix that portions of the tissue above the internal os may be affected with similar disease, either secondarily or primarily, whether by continuous spread of the degeneration or by the formation of an independent focus. Such a possibility is sufficient to make total extirpation preferable to high amputation; for the slightly increased risk of the operation is much less important than the terrible danger of relapse, or rather of the continued existence and progress of an undiscovered focus of disease. What surgeon would be content to excise a carcinomatous nodule with the adjacent parts only? Do not conscientious operators try to remove not only all portions of the mammary gland, but even the contents of the axilla, because by doing so, although the primary mortality of the operation for cancer of the breast is somewhat increased, the chances of relapse are diminished in a much greater proportion.

In regard to the diagnosis of cancer of the cervix, I shall say little, as the subject is elaborately discussed in all the text-books. In many cases the diagnosis is

<sup>1</sup> Read by invitation before the Obstetrical Society of Boston, March 14, 1891.

perfectly simple, but in others it can only be made by the microscope. I will only emphasize here the manifest duty of the general practitioner to make a careful physical examination of women who complain of irregular hæmorrhage; especially when they are over thirty years of age is the existence of cancer to be considered, and many valuable lives would be saved if physicians would examine their patients carefully instead of prescribing for menorrhagia and metrorrhagia, as if these were diseases in themselves and not mere symptoms, imperatively demanding an accurate diagnosis. When examination, however, is inconclusive, and merely shows a raw and angry condition of some part of the os externum, usually the site of a laceration from some previous labor, particularly if the condition is intractable under treatment, and the place bleeds easily when touched, a sufficient piece should be removed to permit of a microscopic examination by an expert. For this purpose a wedge-shaped fragment should be excised with scissors, going rather deeply into the tissues of the cervix, or if the affection seems to be more within the cavity of the uterus a suitable fragment can be obtained by means of a curette. If bleeding is severe, and is not controlled by styptic cotton, a suture may be necessary to stop it. When the tissues are friable, so that a considerable portion can be removed with a sharp spoon or with the finger-nail, the affection is almost certainly malignant.

In regard to malignant disease of the body of the uterus, I suppose that there is no question but what total extirpation is imperatively indicated, whenever it can be accomplished, and as soon as a diagnosis can be made. Here again the microscope is of the greatest advantage, for the hæmorrhages are usually such as to call for curetting, and diagnosis of malignancy can be made without difficulty from the masses removed by the curette, not only by the aid of the microscope, but often by their gross appearance, the fragments being whitish, thick and friable and quite unlike mucous membrane.

Here again the greatest service can be done by our profession by teaching the women who are under their care that irregular hæmorrhages at the time of the menopause, especially when protracted and severe, are not to be simply considered as almost necessary phenomena of the change of life.

The beliefs of the laity in medical matters are not mere superstition, but usually reflect pretty accurately those theories which were current in the medical profession from twenty to forty years previously. The women of the present generation are vastly better informed about their generative organs and functions than were their mothers or grandmothers. It is very probable that they know a great deal more about these subjects than is good for them; but at any rate one thing should be assiduously taught and insisted on by the profession, and that is that irregular and profuse hæmorrhages, especially after the menopause, are often of very serious import. In this connection I wish to call attention to a condition which is not very common, and which is not usually well understood, namely, to a transition state of adenomatous thickening of the mucous membrane of the body of the uterus in elderly women, which finally degenerates into carcinoma. In these cases after the menopause has been established, perhaps for several years, irregular hæmorrhages begin, which are usually relieved by curetting; this operation has to be repeated many times, at intervals

of a few months, very considerable masses of tissue resembling mucous membrane being removed, which under the microscope are found to be composed almost entirely of glands with very little intervening connective tissue. All these cases eventually terminate in carcinoma, and therefore total extirpation should not be delayed, although I have known the radical operation to be discontinued by a pathological expert, who misinterpreted the microscopical appearance as implying a benign hyperplasia of the uterine mucous membrane; finally, however, hysterectomy had to be performed.

I have now performed the operation for vaginal hysterectomy twenty-one times, in every case for cancer, or malignant adenoma, of the uterus; the youngest patient was twenty-six, the oldest sixty-six years of age. All the patients recovered from the immediate effects of the operation, except one, who was operated upon in another State, and was not seen by me after the operation, and who died at the end of a week with symptoms of peritonitis with very obstinate vomiting. Another patient, one of the early cases, where the disease had invaded the left broad ligament, so that the clamps had to be applied in unhealthy tissue, did very well for ten days, so that she was considered out of all danger. She felt so well that, without permission, she sat up in bed to take her supper. The same night the patient in the next bed heard her make a strange noise, and saw her make a convulsive movement; the night nurse, who quickly went to her bedside, found her dead. No autopsy was made, but it was thought probable that death was attributable to embolus from the detachment of a clot in the stump. All the other cases recovered, having a remarkably easy convalescence. One case was operated on ten months ago in Rhode Island, for Dr. Mitchell of Providence, where the disease had advanced in the anterior and posterior cul-de-sac, so far that the removal of what remained of the uterus was performed as the best method of taking away as much of the disease as possible and of giving security against hæmorrhage, although it was certain that all of the carcinomatous tissue was not removed. This patient, however, was able to get up, and did well for several months after the operation, and is still living. Subtracting from the whole number of twenty-one cases the one which died from the operation, and three cases (including the two above mentioned) where the whole of the diseased tissue could not be removed, and one of whom died, there remained seventeen cases where with greater or less difficulty the whole uterus was removed, and the clamps applied to apparently healthy tissue, six of these operations have been performed within the last six months, and are therefore unavailable as far as regards the question of recurrence, at any rate the patients are doing well so far. Of the eleven other cases which recovered, and which have been operated on for a year or more, three are dead, and one will soon die, from recurrence of the cancer. The other seven are in excellent health, as well as the six recent cases above referred to. With a single exception, already mentioned, the convalescence was extremely easy and uneventful. There was no elevation of temperature nor any sign of peritonitis. The scars left in the vagina were smooth and painless. One patient has since married, and another proposes to commit matrimony at an early date. In two cases the bladder was injured at the time of the operation,

and in three others the patients began to "leak" a few days after the operation. In all these cases, however, I had no difficulty in repairing the fistula at the time or at a later date. In two it closed of itself. In one the opening into the bladder was complicated by a severance of the ureter, which emptied into the vagina; I succeeded, however, in passing a sound through the urethra and bladder out into the vagina, and then into the contiguous opening of the ureter. Then by a plastic operation I covered the sound in with mucous membrane, so that the ureter was turned into the bladder and gave no further trouble. The original operation in this case had been a very difficult one, and the cervix had already been curetted and canterized in another hospital.

In regard to the technique of the operation, I will not occupy much of your time. I always use clamps instead of ligatures, not only because thereby the operation is shortened, and hemorrhage more safely controlled, but because the weight of the handles of the clamps insures thorough drainage, and the tissues seized by the clamps can be crushed and the lymphatics obliterated before the scissors are used, thus diminishing the chances of cancerous infection of the lymphatics of the stumps and broad ligaments, and permitting the severance of the latter further from the uterus than would be possible by the use of the ligature alone.

I have brought here for your inspection all the uteri removed by total extirpation in the cases above referred to; a study of these will give a better idea than any description of the condition of the cancerous uterus; of the tendency of the affection to extend above the internal os; of the varying distance both in front and behind at which the peritoneum is reflected from the body or neck of the uterus; of the adhesions which may tie down the fundus, or hold the tubes and ovaries fixed, thereby greatly complicating the operation and rendering it extremely difficult. Of all the twenty-one cases, I can recall only five where the organ could be easily drawn down and the clamps applied with the facility described in some accounts of the operation. In two cases there were present small ovarian tumors, which were removed through the vaginal opening; one was a dermoid cyst, one a multilocular cyst.

Besides the cases reported above I have twice opened the abdomen from above, and once from the posterior cul-de-sac, to decide as to the feasibility of total extirpation, but have found the disease spreading to such an extent as to contraindicate any attempt to perform such an operation. All of these three patients recovered from the exploratory incision without any difficulty.

The preparations exhibited under the microscopes, and others which I have brought to-night, show very well the appearance of carcinoma of the uterus. Some of them I made myself, and some were kindly made from my specimens by Dr. Haddock of Beverly and Dr. Cottrell of Boston. I call particular attention to the preparation showing the carcinomatous degeneration of a uterine gland, and to that displaying the peculiar structure of malignant adenoma.

In regard to the limitations of this operation, they are well defined, and the results as to recurrence have been much better since the operation has been refused in unsuitable cases. The main point is to be sure that the disease has not invaded the broad ligament to such an extent that cancerous tissue would have to be left within or beyond the grasp of the clamps. This usu-

ally can best be determined by examination through the rectum, especially when the uterus is drawn down with the bullet forceps or tenaculum. Of course, cases where the disease has spread over the vagina, or has involved the tissues about the rectum or bladder, or where there are deposits in the pelvis, or metastases in other organs, are unsuitable for operation. Secondly, the uterus must be reasonably movable, so that it can be drawn down, as the presence of old adhesions, even when not of a malignant nature, is a very serious complication, which can only be overcome by carefully and skillfully separating the adhesions with the fingers in the space of Douglas, as was done in some of the above cases, or by making an abdominal incision for this purpose, which of course greatly increases the severity of the operation. Thirdly, the vagina and the space between the pelvic bones must be wide enough, in comparison with the size of the tumor, to allow the removal of the latter. This condition applies particularly to women who have never had children, and in whom malignant disease generally affects the body of the uterus, whereas in women who have borne children the cervix is usually first affected.

Operation may also be contraindicated by the presence of serious disease of other organs, or by great weakness from cachexia, or from loss of blood, although in the latter condition a preliminary operation of scraping and burning out the diseased mass, followed by rest in bed, attention to cleanliness, liberal food and tonics, will sometimes bring the patient into a condition which permits the performance of a radical operation.

## CYSTS OF THE LABIUM.<sup>1</sup>

BY W. M. CONANT, M.D.

This title applies to all cysts of the female perineum that protrude into either labium.

It is hardly necessary before this Society to say anything about the female genitals, yet a few points about the female perineum may make more clear certain points that are important when treatment is considered.

It should be remembered that the vagina as well as the urethra has its opening in the triangular ligament.

After removing the skin and superficial fascia there is exposed the transversus perinei, composed of a few weak muscular fibres, which passes from the ischium inwards behind the posterior commissure to the central perineal point. There is also exposed the ischio-cavernosus (erector clitoridis) sheathing the corpus cavernosum. The sphincter vaginae (bulbo-cavernosum) arises from the central perineal point behind, and passes each side of the vaginal orifice to unite in front. It overlies on each side the erectile mass which corresponds to the urethral bulb. These three muscles bound a triangle, and should be removed to see the erectile tissue beneath.

The vaginal bulbs are two plexuses of veins on each side of the opening of the vagina and vestibule. They are narrow in front, and wide and divergent behind; convex externally and covered by the sphincter vaginal muscles; concave internally, and lined by the mucous membrane of the vagina. When the corpora on each side are separated, the deep triangular ligament is brought to view. This is wider but much

<sup>1</sup> Read by invitation before the Obstetrical Society of Boston, March 11, 1891.

weaker than that of the male. Above the union of the base of this ligament with the deep pelvic fascia lie the glands of Bartholin (vulvo-vaginal). They lie in the upper and anterior surfaces of the vagina, closely connected to the mucous membrane, and beneath the sphincter vagina. The ducts pass forward and open immediately external to the hymen at the middle point of the labial wall of the vaginal orifice, within the labium minus, and are, therefore, just below the vaginal bulbs.

I agree with Tillaux that this gland is an extremely hard one to find on the cadaver, and like him I have searched in vain; therefore, I agree with the views of M. de Sinéty that the gland is very diffuse, and is composed of a great number of small glands irregularly placed, and separated from one another by the connective tissue and fascia.

A glance at a plate of the perineum in any anatomy will make clear the fact that there is a triangular space which has three muscles for its side. This space is covered anteriorly by the labia on either side. A cut, therefore, to the outer side of the labium major would be a safe distance from the vaginal bulb and corpus cavernosum. There would also remain a clear space for the dissection of a cyst. There are no important vessels to cause hemorrhage in this triangle, as the perineal vessels are below the ligament, and only the superficial vessels would be cut.

Cysts may occur in the vulvo-vaginal glands, and are true retention cysts. They may occur in the mucous glands of the labia; from retention in Gartner's canal, a fetal structure usually obliterated; in the capsule about old blood clots and in enlarged lymphatic spaces. The wall is thin, but firmly adherent to the wall of surrounding parts. The contents are usually a clear watery fluid, but may be dark brown, thick, or even purulent.

These cysts may be confounded with hydrocele, hernia, and abscess of the vulvo-vaginal duct (not gland as usually spoken of). A differential diagnosis can be made by the history, the soft, fluctuating feel, the lack of sensitiveness, the slow growth and by the use of the hypodermic needle.

Small cysts will often disappear without treatment, showing that the retention has been overcome. An attempt should be made to find the duct in all cases, and if possible evacuate the contents. The most common method seems to be to incise as if the cyst were an abscess and then evacuate. In a short time, however, the tumor returns. In small cysts an injection of carbolic acid (1-20) is claimed to give excellent results. Another method is to incise the cyst on its mucous membrane and use caustic on the lining membrane; but the wound heals slowly, and leaves a large scar. When the cysts are so large that they cause great discomfort in sitting or walking, and even prevent coitus, some other method of treatment than above mentioned is needed. The best method is dissection. Mann in his article on "Diseases of the Vulva," says: "If the cyst be superficial, it [dissection] is undoubtedly the most satisfactory method, but if it is very deep and large, the operation is likely to be a difficult, if not a severe one, as the hemorrhage is apt to be considerable."

This should be made still stronger. In my opinion dissection is the best method whether the cyst is superficial or deep.

The operation in the two cases which I shall report

was performed as follows: The vulva was washed with a solution of corrosive sublimate (1-2000), and a sublimate pad was worn the night before the operation. One hour before operating two ounces of whiskey and one one-hundredth of a grain of sulphate of atropia were given. After the patient was etherized the parts were scrubbed, and the hair shaved off. Then an incision was made to the outer edge of the labium, and the cyst dissected out without rupturing the sac. The wound was washed only with hot, filtered water to stop bleeding, and then sewed up with silk sutures. No drainage-tube was inserted.

It is hardly necessary to state that instruments, needles, thread and sponges should be sterilized in an Arnold or Chamberlain sterilizer for fifteen minutes before using.

The reasons for preferring this operation are these:

(1) Dissection is the best method. The cyst being removed no further trouble can occur.

(2) The incision is made in the skin at the most favorable anatomical point for the dissection.

(3) The mucous membrane is left intact.

(4) The wound heals so that only a line scar remains.

(5) Hemorrhage is slight and easily controlled.

(6) Urine can be passed without coming in contact with the wound. Hence not necessary to use a catheter unless there is retention.

(7) An aseptic dressing can be applied and remain on for several days.

The reports of the following cases were kindly made for me by Dr. Underhill, formerly house-officer at the St. Elizabeth's Hospital. The first one is a case of retention in the mucous glands of the labium. The second is probably a cyst of the vulvo-vaginal glands, and from its unusual size is interesting:

CASE I. Mrs. P., age thirty-four. Married twelve years. Family history good. General health good. Enters the hospital complaining of pain in left side and back. Examination showed retroversion with adhesions. Much improved by packing.

June 9th, swelling noticed in right labium. July 27th, cyst, size of an English walnut, removed. July 31st, four days after operation, stitches removed. Wound healed by first intention. August 3d, one week after operation, discharged.

CASE II. Mrs. A., age forty. Married twenty-one years. Enters the hospital because of a lump in left side of the vulva, which first appeared three years ago. Has been growing steadily larger, and is very painful when sitting or walking. Coitus has been so painful as to be almost impossible. Examination revealed a soft, fluctuating tumor in the left labium, the size of the fist; very tense; the mucous membrane within the vagina somewhat eroded. Entrance to the vagina was pushed to one side, and the finger was introduced with some difficulty.

July 10th, cyst dissected out under ether, which was as large as a goose egg. Contained a thick grumous fluid. Stitches removed on the sixth day. Two weeks after operation patient discharged well.

HISTORY OF THE MICROSCOPE.—It is proposed to organize an international exhibition of everything connected with microscopy, to celebrate the third centennial of the discovery of the microscope. It has been suggested that it should occur in Antwerp during the coming autumn.

THE SPECIFIC AND NON-SPECIFIC TREATMENT OF PULMONARY CONSUMPTION.<sup>1</sup>

BY THOMAS J. MAYES, M.D.,

*Professor of Diseases of the Chest in the Philadelphia Polyclinic.*

It goes without saying that the successful treatment of pulmonary consumption depends entirely on a correct and rational view of its origin. On this ground, there can be no division of opinion. Unfortunately, however, one part of the profession holds that the tubercle bacillus is the sole cause of the disease; while the other part believes that the disease depends on numerous other causes, and that the bacillus is merely one of its products or concomitants.

Now, it must be confessed that diametrically opposite opinions on a question of such tremendous practical and public importance is no great credit to a profession which is justly proud of her logical conquests, and which rightfully rejoices in her scientific achievements and in her work of philanthropy. Especially is this a misfortune when we consider that the whole difficulty rests on an erroneous interpretation of the fundamental terms which are involved in the question; and in endeavoring to prove this, I desire it to be perfectly understood at the outset, that I yield to no one in my admiration of, and I might even say in my veneration for those pains-taking explorers who so patiently and assiduously devote their life and energies to the investigation of this fearful malady. But I do not regard this as a question of personal reverence. It is one which must determine the true relation of the consumptive to his family, to his friends and to society; whether or not he is to be looked upon as a centre of infection, a source of danger, and liable to spread the disease among those who are well.

Where, then, lies the fundamental misapprehension? It is (1) in affirming that, because a disease is capable of being communicated from one animal to another through inoculation, that, therefore, it must be contagious or infectious among the human species; (2) in holding that the disease (tuberculosis) which is produced artificially in animals through inoculation is the same as that (consumption) which is naturally produced in man; and (3) in assuming that, because an immunity can be created in animals by inoculations with a modified form of the tubercle virus, the same can be done in man. Furthermore, there is no warrant for believing that a disease can be cured by antagonistic inoculation unless it is clearly infectious or propagated from man to man through contagion.

The whole inception and progress of the infectious theory of consumption rests on animal experimentation, and recent history still reverberates with the assurances that the key to the cure of this disease was lying waiting in the lap of the experimentalists, whose dicta were to be blindly accepted whether they accorded with clinical experience or not. I am a firm and positive believer in the immense good which comes from well conducted laboratory research, and I think I have given sufficient practical evidence of my high appreciation of such work; but I recognize the fact that the great bane of modern medicine is the tendency to subscribe to the premature conclusions of experimentalists which are wholly unsupported by bedside experience.

Professor Semmola, of Naples, Italy, well strikes the key-note of this error, when he says: "It is pain-

ful to see these men carried away with this enthusiasm of Koch's fluid when they know that such a wide gulf exists between theory and practice, and when the very laws of scientific pharmacology and rational therapeutics are violated. The mistake exists in neglecting to see the gulf that lies between the laboratory and the clinic where all such fine dreams are blasted."

I am free to say that the mortification of professional pride, and the shock to public confidence recently perpetrated in the name of a specific cure for consumption, would all have been saved if we had raised our standard of treatment higher than the walls of the laboratory, and planted it on the solid and rational ground of practical experience.

I am not unmindful, however, that those who indorse the contagion theory claim that, aside of experiments on animals, there is ample clinical evidence to justify their belief. Let us briefly examine these claims. Their chief argument is the work of Cornet, who investigated the death-rate from consumption among the nursing members of the Catholic convents and monasteries in Prussia, and found that this disease causes 62.88 per cent. of all their deaths.<sup>2</sup> This is, indeed, a high death-rate, but it does not demonstrate the contagious nature of consumption. It merely shows, what was well known before, that this disease prevails largely among those who lead in-door and confined lives. According to Dr. Baer's research,<sup>3</sup> the death-rate from consumption among German prisoners is greater, ranging from 64 to 90.9 per cent. Another point which destroys Cornet's conclusions entirely is forcibly brought out by Dr. Baer's statistics. These show that prisoners who suffer solitary confinement, and who have, of course, no personal contact with any outside sources of the disease, are more vulnerable to consumption by 20 per cent. than those who are allowed to associate with each other.

Another argument is that houses in which consumptives died are centres of infection. This is principally based on the research of Dr. Flick, who believes from his investigations that 20 per cent. of the houses in the fifth ward of the city of Philadelphia are so infected. It is interesting to observe, however, that Dr. Flick's conclusions are not corroborated by other observers equally competent who have studied the question of house infection. Dr. Langerhans, who practised medicine for nine years in Madeira, an island which is visited every winter season by about 400 consumptives, states<sup>4</sup> that these invalids are lodged, boarded, and in great part nursed, by English colonists, varying from 210 to 250 in number, who live in about 100 houses. The rooms, which are occupied by consumptives in the winter, are reoccupied by the resident families during the summer — thus insuring the closest intermingling of the well with the sick. House infection should certainly make its influence felt here, but the health records, which have been accurately kept since the year 1836, show that only four of the English colonists died from consumption during all this time, and that one of these suffered from the disease before he came on the island.

Dr. Adams, of Colorado Springs, states in a private communication to me, that Colorado Springs has been a health resort for about seventeen years, and comprises about 11,000 inhabitants, and that the majority

<sup>1</sup> Read before the meeting of the Pennsylvania State Medical Society at Reading, June 3, 1891.

<sup>2</sup> Medical Press and Circular, February 25, 1891, p. 135.

<sup>3</sup> *Zeitschrift für Hygiene*, vol. vi, p. 15.

<sup>4</sup> Ueber das Vorkommen von Phthisis in dem Gefangnissen, 1884, *Archiv für Ethnologie der Phthisis*, Virchow's Archiv, 1884, vol. xcv, p. 289.

of the rooms in the boarding houses are, and generally have been constantly occupied by consumptives. Yet, after a diligent search among the physicians of that place, some of whom resided there from the first, he could only find a record of seven cases of consumption which originated there during this time; and so far as he could ascertain, none of these were especially exposed—at least none were husband, wife or sister who had charge of another consumptive.

Dr. Haupt, one of the resident physicians of Soden, a beautiful watering resort for consumptives, in Germany, says that there are one hundred and one families, whose members with the aid of servants, lodge and nurse consumptives and other invalids during the summer season. During the winter the same rooms are reoccupied by the members of the landlords' families. This has been going on for thirty-three years, and during this time there were exposed to this contagion, if so it may be called, 653 persons, fifteen of whom died from consumption, but in most of these the source of the disease was traceable to inheritance, to colds and exposure, but none of them to contagion.

Now when these facts are connected with other well-known facts, such as the statistics of the Brompton Hospital for Consumption in London, and the Friedrichshain Hospital in Berlin, which fail to show a single case of contagion among 262 physicians and clinical assistants, and 1,017 nurses—the former during thirty-six years and the latter during sixteen years, the declaration of Dr. Detweiler, that during fourteen years not a single case of consumption was contracted among the nurses and employees in his hospital for consumptives at Falkenstein; or the fact that among a collection of 1,626 cases of consumption among married people (for particulars I refer to my address on Hygiene published in last year's Transactions of this Society) the same disease existed in both couples only in 44 instances. I think no further proof is needed to demonstrate that consumption is not propagated from person to person through contagion.

I hope I shall be the last one to deny to my colleagues on the other side, the same honesty and conscientiousness of purpose as I ascribe to myself; but should this make me willing to brush aside this weighty mass of clinical testimony which is diametrically opposed to the contagion doctrine, and to accept as my guide, principles of treatment which are conceived in theory and born of fancy, and which have nothing to support them in bedside experience? He who has been a diligent observer during the last ten or fifteen years, must be aware by this time that every specific measure which has been proposed for the cure of consumption, from benzoate of soda, and hot air inhalations to tuberculin, has been a dismal failure, in spite of the fact that they have all been shown to possess strong antibacillary powers. Glance at the beggarly results which have been obtained from tuberculin. According to recent official reports,<sup>1</sup> fifty-five in number, issuing from the clinics, polyclinics, and pathological institutes of the Prussian University, only about one per cent. (10) of 352 consumptives, who received the specific treatment, were cured. This is, indeed, a very diminutive proportion of cures when we reflect that all but one of the latter were in the first stage of the disease. There cannot be the least question that so far as the treatment of consumption is concerned, the bacillus

theory leaves the profession exactly on the same level which it occupied ten years ago. Not only did it not advance the interests of pulmonary therapeutics, but it deflected research into channels of error, and served as a barrier to an investigation of the true causes of consumption.

Let us now relinquish the gloomy side of this picture and turn to the hopeful experiences of those who practically disregard the teachings of the bacillus theory, and treat the disease according to its clinical indications. First of all I shall refer to the experience of the late Dr. Brehmer in his world-renowned institution at Görbersdorf, in Germany. In 1887 he gives the statistics of 150 cases of consumption which he treated, 12 of whom were in the first, 80 in the second, and 58 in the third stage. Of these cases, 15.3 per cent. were cured, and in 11.3 per cent. the disease was arrested. Of those in the different stages he cured 50 per cent. in the first, 20 per cent. in the second, and 1.7 per cent. in the third stage of the disease.

In 1888, he gives the statistics of 554 cases which he treated, of whom 49 were in the first, 310 in the second, and 195 in the third stage. Of those in the first stage he cured 36.1 per cent., in the second, 9.7 per cent., in the third, 0.5 per cent.

The results reported in the Sixth Annual Report of the Adirondack Sanitarium, under the supervision of Dr. Trudeau, are not less encouraging. Fifty-two patients were treated in the following stages: 21 in the first, 18 in the second, and 13 in the third. Of those in the first, 13 or 61.90 per cent.; in the second, 2 or 11.11 per cent.; in the third none were apparently cured—showing a total of 28.84 per cent. cures. Besides these it is shown that there are 11 cases, or 21.15 per cent. in whom the disease is arrested, that is, in whom all constitutional disturbance has disappeared for several months, but in whom the bacilli, cough and expectoration are still present. It may not be too much to hope that a number, and possibly most of the arrested cases will in time go to swell the list of the cures.

Similar favorable testimony concerning the non-specific treatment of consumption is also attested by other institutions of a like character, notably by that of Dr. Detweiler, of Falkenstein. In fact such institutions demonstrate that the successful treatment of pulmonary consumption is no longer to be disputed, and they show that no chronic medical disease is so amenable to treatment as pulmonary consumption.

A most interesting point in this question is the fact that there is a consensus of opinion as to the methods which bring about the best results in the treatment of this disease. The first is *an institution* in which the patients are under the immediate and direct supervision of intelligent physicians and nurses. In regard to these, Brehmer<sup>2</sup> in no uncertain tone, says: "Special institutions for the treatment of consumption give the greatest promise of cure." Dr. Trudeau<sup>3</sup> states: "If anything is to be done for those who are both poor and consumptive, it cannot be done outside of an institution." Many other physicians who have had experience of this sort are equally emphatic in their opinion on this subject.

The second is *rest*, or at least a rigid control of the

<sup>1</sup> By "apparently cured" is meant when the rational signs of the disease and the bacilli have been absent for at least three months. I think it is but reasonable to assume that such cases are cured.

<sup>2</sup> Therapie der Chronischen Lungenschwindsucht, 1887, p. 83.

<sup>3</sup> Transactions of American Climatological Assoc., 1889, p. 168.

<sup>4</sup> Die Wirksamkeit des Koch'schen Heilmittels gegen Tuberculose.

physical movements of patients. On this subject Brehmer says: <sup>10</sup> "This much I can assert, that all fatigue is an injury and a poison to the consumptive. . . . The healthy individual rests because he is tired, but the consumptive must rest so that he cannot become tired."

One of the important instructions in Dr. Trudeau's Sanitarium is, "When feverish, patients will do well to make as little exertion as possible. Fatigue, when induced in persons still having active disease, is sure to be followed by loss of appetite, fever, exhaustion, and even sweating."<sup>11</sup>

Dr. Detweiler, in his report for 1886, states that every patient who is not confined to bed must repose in the open air on a reclining chair throughout the greater part of the day.

Dr. Volland, of Davos, who has had extensive experience in the high altitude treatment of consumption, declares <sup>12</sup> that rest in the open air is the first duty of the consumptive patient, and that, if he is able, he is allowed to sit out-of-doors, and if not, he is confined to bed in a well ventilated chamber.

This feeling to regard rest as such an important element in the successful management of consumption is not confined to these and other public institutions, but is also shared by private practitioners, and it is based on the sound pathological reason that consumption is not a local disease of the lungs, but one which implicates the whole constitution. A consumptive must be looked upon as one verging on physiological bankruptcy. His whole strength is already absorbed in the performance of the necessary functions of life, frequently carried on imperfectly. His digestion is weak, his bowels may be disordered, sleep is restless and disturbed, there is a waste of tissue owing to the fever, and his muscular power is impaired to such a degree that a short walk or a small amount of physical exercise saps his strength, and may wholly disable him. Yet strange and paradoxical as it seems, weak as he is, he persists in the belief that exercise is the one thing needful for his restoration. This feeling is not confined to consumptives, but lives in behest of a strong public sentiment. It is builded on the knowledge that in health exercise gives strength. But what an enormous difference between the body in a normal state, and when suffering from a chronic wasting disease like consumption! The two conditions may be illustrated by comparing a business man who is threatened with insolvency with one whose credit is good. If the former pays out as much as he takes in, his finances will always be in a crippled state, and he will be in constant danger of going to the wall; but if he halts—that is if he diminishes his expenses and maintains or increases his income—his capital will accumulate, and in time he will be able to compete with other capitalists. But the business man whose credit is unimpaired, goes on and invests all his surplus capital—that is, he exercises his financial strength to the utmost limit of prudence—and thereby enhances and improves the integrity of the institution which he represents. So it is with the taking of exercise. If this is to be beneficial, a certain amount of strength must be possessed by the individual before he begins it, and by putting this strength to proper use it will grow and accumulate; but he who has no, or very little

strength at the outset, must reduce his expenditures or his waste, and enlarge his income, or else go into physiological bankruptcy. We must realize that with the consumptive, it is wholly a question of constitutional resistance; that when he is weak the disease is strong and advances; that when he is strong the disease is weak and recedes; and that the force which he expends in performing exercise, deducts so much from his total vitality, and allows so much less for the body to cope against the disease, and to perform the essential functions of life.

Moreover, there is a perfect agreement in these institutions in regard to the great utility of supplying nutritious food in the most concentrated form; of reducing high temperature with antipyrin, phenacetin, and antifebrin; of checking the waste which is occasioned by cough, expectoration, sweats and diarrhoea; of employing pneumatic and climatic treatment; and in fact of everything which goes to enhance the vigor and vitality of the body.

I think I am justified in saying that hard, cold, positive facts are the best crucial tests to which a theory can be submitted in order to ascertain its correctness. The specific cure for consumption is utterly condemned, when compared with the general treatment of this disease on such a basis. How would mercury rank as a specific in syphilis, or quinine in ague, if their curative results were as hapless as those of tuberculin? Even if a specific cure for consumption were possible, it is difficult to see its need in view of the large number of cures, as I have shown, annually made by other means. From my own personal experience, I can testify that there is no chronic disease which responds more readily and more promptly to persistent and well directed general treatment than pulmonary consumption; and there is no reason to doubt that with the advance of the scientific study of the disease the percentage of cures will increase. A specific cure for consumption is not of so much consideration now as a study and a development of the lines of treatment which have been shown to hold out such a magnificent measure of enduring success.

One more thought and I am done. Ever since the failure of tuberculin became generally palpable, there arose a feeling in the minds of many of his followers, that Dr. Koch had made a serious mistake in the practical application of his theory, and that eventually great therapeutic results are bound to flow from it. Dr. Koch is not in error, but is more consistent than many of his disciples who follow him in the distance. He has a logical belief in his theory, and knows what the practical application of tuberculin implies better than any other living being. There cannot be the least question concerning his ability to cure by inoculation, the disease which he artificially induced in animals; and if consumption in man were caused through contagion or inoculation, or was of the same nature as the disease which he produced in animals, it would be perfectly reasonable to hope that he could cure the consumption in the human family. But the disparity which exists between that which *is* and that which *seems*, is a vortex which has stranded and annihilated many an idea. This is not the first time that the contagion theory of consumption has come to grief. A century ago the government of Naples concluded that consumption was an infectious disease, and practised the most rigorous isolation of those who suffered from this disease, for more than fifty years. The results

<sup>10</sup> Mittheilungen aus Dr. Brehmer's Heilanstalt, 1889, pp. 43, 45.

<sup>12</sup> Die Behandlung der Lungenschwindsucht in Hochgebirge, p. 18.

were abominable. Reliable historians inform us that besides causing untold misery, these laws were not of the slightest service in diminishing the death-rate from this disease.

Should we not profit by these dearly-bought experiences? Is it not high time that we take an account of our bearings and begin to recognize that he who hugs the delusion that consumption will be cured or prevented through the miraculous operation of some anti-bacillary agent or process, will only live to reap "from the hopes which around him he sows, a harvest of barren regrets?"

#### SOME PRACTICAL POINTS IN THE DIFFERENTIAL DIAGNOSIS OF IRITIS AND CONJUNCTIVITIS.

BY FREDERICK E. CHENEY, M.D.,  
Assistant Surgeon to the Massachusetts Charitable Eye and Ear Infirmary, Ophthalmic Assistant to the Out-Patient Department of the Massachusetts General Hospital.

THE importance of making a correct and early diagnosis, in cases of iritis, and of using atropine, or some other mydriatic, until the inflammation has subsided, is evident, when it is considered that many patients are afflicted with permanent poor vision and not a few with blindness, as a result of improper treatment in this disease. In most of these cases the trouble has probably been mistaken for conjunctivitis, the eye has been treated with "borax and camphor," or some other mild astringent collyrium, and a disease which usually terminates favorably when treated from the beginning with atropine, terminates most unfavorably.

It is not my intention in this paper to present an exhaustive treatise on this subject, but simply to make prominent two or three points of difference between these two diseases that are most constant and that can usually be easily recognized. The presence or absence of pain, and its character and situation, if present, is a symptom of great value, and cannot be too carefully investigated. In conjunctivitis, there is often no pain, other than a feeling of "sticks and sand" in the eyes, while at other times pain of moderate severity is complained of and is referred by the patient to the eyeball. In iritis, on the other hand, pain is usually a prominent symptom, it is paroxysmal in character, coming on most frequently in the early hours of the morning, and is not situated to any degree in the eyeball itself, but in the brow and temple, sometimes extending over the entire side of the head. If this neuralgic pain is of great severity, especially if accompanied by a marked rise of temperature and a loss of appetite and flesh, the redness of the eye may be overlooked both by the patient and physician, or regarded simply as a congestion secondary to the neuralgia. Neuralgia of the temple and brow, in connection with redness of the eye, should always make one suspect iritis as the cause, and should lead to a careful examination of the pupil, as to its size and reaction to light. Having placed the patient facing a bright light, the well eye is to be covered, while the inflamed eye is to be shaded from the light with the examiner's hand. If the case is one of conjunctivitis, the pupil will quickly dilate when the eye is shaded and again contract when exposed to light. If iritis, however, it will be noticed that the pupil is smaller than normal, and that it reacts little or not at all when the eye is alternately shaded and exposed. These three symptoms, redness of the eye, neuralgic pains in the

temple and brow, and a pupil which reacts sluggishly or not at all to light, are most valuable diagnostic symptoms in iritis, and when present, should leave little doubt as to the nature of the disease. Intolerance of light is usually present in iritis, but may also be present in conjunctivitis. The iris tissue is usually discolored in iritis, the change at times being very noticeable, while at other times it is slight and can be easily overlooked. The character of the vascular injection should of course be noticed, the circumcorneal vessels being injected in iritis, and the conjunctival vessels in conjunctivitis. It is not uncommon, however, to see a moderate injection of the circumcorneal vessels in conjunctivitis, or to see a considerable injection of the conjunctival vessel, and even oedema of the tissue, in iritis.

To emphasize what has already been said, the symptoms most to be depended upon in making a diagnosis of iritis, are, redness of the eye in connection with neuralgic pains of the temple and brow, and a contracted pupil that reacts sluggishly or not at all to light. Sub-acute and chronic cases are at times met with in which the pain is slight or absent, and the circumcorneal injection but poorly marked. The pupil will, however, be contracted and sluggish, and as the trouble often exists for some time before medical advice is sought, firm adhesions between the pupillary border and lens will probably be found after atropine has been used. Also, in acute iritis, pain may not be complained of for the first few days, and in exceptional cases may be absent during the entire course of the disease. The absence of supra-orbital and temporal pain, therefore, although a most frequent and valuable diagnostic symptom, does not exclude iritis, and the presence of other symptoms must always be looked for. If, after careful examination, a doubt as to the nature of the disease still exists, a safe rule to follow is, When in doubt, use atropine. If the disease proves to be conjunctivitis, the use of atropine for the first day or two will have caused no permanent harm, the mydriasis and paralysis of accommodation passing off within ten days or a fortnight. If, on the other hand, it is iritis, we shall have the pupil well dilated, and if kept so by the use of atropine until the inflammation has subsided, it will be almost impossible for adhesions to form between the iris and the lens.

The value of the early and constant use of atropine in iritis cannot be too strongly insisted upon. A wide dilatation of the pupil is of course the end in view; and while, as a rule, a one-per-cent solution of atropine sulphate used three or four times a day will accomplish this, a more frequent instillation or stronger solution is sometimes required.

#### RECENT PROGRESS IN ANATOMY.

BY THOMAS DWIGHT, M.D.

##### THE RELATION OF THE SURFACE OF THE BRAIN TO THE SKULL.<sup>1</sup>

As we all know, many rules have been given for drawing lines on the scalp to show the course of the chief fissures and convolutions. Absolute accuracy cannot be reached, owing to individual variation. The merit of Professor Langdon's method is that he dis-

<sup>1</sup> Cincinnati Medical Journal, April, 1891.

cards entirely measurements in inches or centimetres, and relies entirely on cranial landmarks. He believes that by this method there is much less danger of error arising from the peculiarities of long and short heads. He is quite right in emphasizing the fact that "the anatomical personal equation, so to speak, of the operator must determine the exact place of application of the trephine." In this connection we will venture to suggest that the point which surgeons need to study most, and which we suspect they study least, is the surface of the brain as shown on a large enough series to present many irregularities. There is no difficulty in getting some part of the fissure of Rolando under the opening made by a large trephine, but there may be great difficulty in recognizing it, if the arrangement be even a little irregular.

The following are the chief features of Dr. Langdon's method: (1) Draw a *fronto-occipital* line from the base of the external angular process at the level of the highest point of the orbital arch to the external occipital protuberance. This will mark the base of the brain, excepting the end of the temporo-sphenoidal lobe, which comes below it. About the posterior third of this line indicates the upper border of the horizontal part of the lateral sinns. Then draw two vertical lines: (2) The *zygomatic-vertical*, from the greatest convexity of the zygoma upward. The lower point of this corresponds to a concavity in the lower border of the zygoma, just in front of the tubercle of its anterior root, easily felt in the living. (3) The other is the *parietal-vertical* running through the greatest prominence of the parietal eminence and the posterior border of the mastoid process. The *Rolandic line* indicating the fissure is drawn from the top of the last line downwards and forwards towards the intersection of the *fronto-occipital* and *zygomatic-vertical* lines, but stopping a little short of it. One more line, the *fronto-parietal*, runs from the angular process to the parietal eminence. Its posterior two-thirds are nearly parallel with the chief limb of the fissure of Sylvius, which lies less than half an inch below it. The crossing of the *fronto-occipital* and *zygomatic-vertical* lines indicates the tip (we should say the upper part of the tip) of the sphenoidal lobe, and a trephine would expose the bifurcation of the middle meningeal artery. (It seems to us that the point of division must at least occasionally fall lower.) A medium sized trephine applied at the crossing of the *fronto-parietal* and *zygomatic-vertical* lines would uncover the bifurcation of the fissure of Sylvius, the posterior extremity of the third frontal convolution and the branching into three of the front division of the middle meningeal artery.

#### THE FORAMEN PTERYGO-SPINOSUM.<sup>2</sup>

It happens once in a while that the posterior part of the external pterygoid plate is continued backward as far as the spine of the sphenoid, and that it is perforated by an opening very near the foramen ovale. This would until recently have been looked upon entirely as a scientific curiosity, but it is a point of great practical importance in the operation of cutting the third division of the fifth pair of nerves at its exit from the skull. If the branches, or most of them, run on the median side of this plate, it is clear that it must be got out of the way. This plate with its perforation was first described by Civinini in 1835 and 1837, and further discussed by Hyrtl in 1862.<sup>3</sup> Civinini showed

that normally there is a membrane in the region in question which occasionally is ossified so as to form the plate, which is then pierced by a foramen. According to him, the middle, meningeal artery, the lingual and inferior dental nerves, and, of course, the internal maxillary artery, all lie on the outside of the membrane. Hyrtl describes also an extremely uncommon little canal in the neighborhood (the *porus crotaphiticobuccinatorius*), with which we do not propose to complicate the discussion, and states that the foramen in the plate already described never transmits any structure.

Dr. v. Brunn has undertaken to find out how frequently the abnormal plate occurs, whether otherwise its place is always taken by a ligament, what is the relation of the branches of the third division of the fifth pair to the structure, and finally what is the condition in apes. He found a complete foramen in 21 of 406 skulls, while processes of bone representing an attempt at the formation of a plate were very frequent. In the fresh state there is, as Civinini had stated, always a ligament which varies greatly from a band to a membrane, but which, we believe, always bridges over an opening corresponding to the foramen in the bone.

We shall not follow our author into comparative anatomy, and regret that he does not say more about the relations of the nerves to this interesting plate, which is of great practical importance. What he does say is very unsatisfactory. We gather that he holds that in man the motor division passes inwards through the foramen while the sensory branches of the third division of the fifth lie outside of the plate. Since the appearance of this paper the writer of this report has had an opportunity to observe these relations on a subject with a well-developed backward extension of the external pterygoid plate, pierced by a large foramen pterygo-spinosum. On one side it was not thought of till the dissection was far advanced when it was found that the inferior-dental and lingual nerve passed through the foramen from within outwards, together with another nerve which had been cut, probably the auriculo-temporal. The muscular branch had been destroyed, but it seemed as if all excepting the nerve of the internal pterygoid must have passed through the foramen. On the other side, which was subsequently dissected with a view to this point, the plate of bone was not present, but a small ligament was found which formed the lower border of a space corresponding to the foramen pterygo-spinosum. The three sensory branches of the third division of the fifth pair passed above the ligament thus showing a corresponding arrangement on the two sides of the head. The writer is informed by Dr. Mixer that he has observed a different arrangement. This should be the subject of a careful study, for the question is of practical importance. The abnormal plate containing the foramen might, one would think, very probably be found differently placed in different bodies so as sometimes to be under the middle of the foramen ovale and sometimes more external or internal to it, with more or less important variations in its relations to nerves.

#### THE RADIO-CARPAL ARTICULATION.<sup>4</sup>

At the meeting of the Association of American Anatomists held in Boston last December, Professor Shepherd, of Montreal, made a communication on this subject. It is generally stated in works on anat-

<sup>2</sup> A. von Brunn: Anatomisches Anzeiger, 1891, No. 1.

<sup>3</sup> Sitzbericht, of Vienna Academy, 1862.

<sup>4</sup> Journal of Anatomy and Physiology, vol. xxx, April, 1891.

only that the scaphoid and semilunar bones articulate with the lower end of the radius, and that the cuneiform is separated from the lower end of the ulna by the triangular fibro-cartilage. Dr. Shepherd showed that, as a rule, the semilunar projects beyond the lower end of the radius, and rests against the triangular fibro-cartilage, which separates it from the ulna. He teaches that in the fresh state a distinct line may be seen on the bone separating the portions articulating with the radius and with the fibro-cartilage. The latter surface varies considerably in extent, and extends more to the palmar than to the dorsal surface. Professor Shepherd found, moreover, that frequently there is a perforation of the cartilage, which he believes to be almost always pathological, and that the surface of the carpus opposite the hole is always the semilunar bone, unless perhaps in cases in which it had worn large when a portion of the cuneiform might also be seen through it.

#### POINTS CONCERNING THE VERMIFORM APPENDIX.<sup>6</sup>

Dr. John Ferguson, Demonstrator of Anatomy at Toronto, has published the results of two hundred careful dissections. The average length was four and one-half inches, and the average diameter that of a No. 9 catheter, English scale. In 123 cases the appendix was supplied with a mesentery of its own, and so placed that its perforation would open directly into the peritoneal cavity. Of these the appendix lay to the outside of the cæcum in 19, to the inside in 18, behind in 75, and ran downward in 11.

"The other group of 77 cases," continues the author, "was specially interesting in the fact that the appendix was so placed and covered by peritoneum that its perforation would open into the subperitoneal tissue, and establish a diffuse form of peritonitis." We regret that Dr. Ferguson has not given us further details in support of a statement so at variance with recent ideas, and made in such general terms as not to carry conviction.

#### VALVES AND MUSCULAR FIBRES IN THE BRANCHES OF THE PORTAL VEINS.<sup>6</sup>

H. Koeppe began a series of studies on this subject before he was acquainted with Dr. W. S. Bryant's work at the Harvard Medical School. It will be remembered that a few years ago Hochstetter discovered valves in the system of the gastric vein, and Bryant found them later in the intestinal veins of the infant. Most of these did not persist in the adult. Koeppe says nothing of the age of his subjects, and indeed one passage inclines us to believe that he made his observations on lower animals. This is a serious defect that deprives his work of much of its value. His results in brief are that the system of the portal vein may be divided into three districts: (1) that of the trunk of the portal vein and its branches, as far as the giving off of the long and short intestinal veins, and in which there is a strong system of both circular and longitudinal muscular fibres and no valves; (2) that of the last-mentioned veins, which have strong circular and weak longitudinal muscular fibres and also valves; (3) that in the submucous layer of the gut, which has neither muscle nor valves.

The most interesting point to us in these studies is that, when the mesentery is tense, the valves work,

and that a bending of the vessel near a valve makes it useless.

*Apropos* of the portal vein, the Anatomical Society of Great Britain and Ireland, sent out four questions in September, 1889,<sup>7</sup> to a number of medical schools. The fourth question was the following: "The order of union of the three great trunks which form the vena portæ, and the levels of their junctions. The recorder is asked to endeavor, as far as possible, to observe and report the existence of valves in any of the tributaries of this vein." There were, in reply to this question, reports concerning only 118 cases. The portal vein is always formed by the junction of the splenic and the superior mesenteric. The uncertain element is the inferior mesenteric. This vein emptied into the splenic in 71 cases, into the superior mesenteric in 39, and into the angle formed by the junction of the two chief veins in eight. The level was noted in 62 cases, in 35 of which it was opposite the second lumbar vertebra. The cases examined for valves were still fewer, and not a single one was found. We presume the subjects were all adults.

#### VARIATIONS OF RENAL ARTERIES.

In view of the constantly increasing importance of abdominal surgery, the origin and number of the renal arteries is of general interest. It should not be forgotten that a comparatively small artery often enters one end of the kidney, which if not thought of could easily be missed in an operation. One of the questions sent out by the British Society bore on this point. The answers gave the results of observations on 419 renal arteries. The arrangement was normal in 312 cases, that is in 74.4 per cent. There was a single artery undergoing immediate division eight times, an arrangement which is hardly abnormal. There was an accessory artery to the top of the kidney from the aorta 29 times, and an inferior one from the aorta 17 times. There was an inferior one from the common iliac of the same side three times. Two arteries not specified occurred 32 times, three arteries 14 times and four arteries three times.

A few of the cases described are worthy of mention. At St. Bartholomew's there was a subject with three renal arteries on the right side and two on the left; and one with four on the left and two on the right.

The following case was observed at University College, London: "The right kidney was large and supplied by a single artery; the left kidney was very small, crescentic in shape, and each extremity received a small vessel, the upper arising from the back of the aorta opposite the renal artery, the lower from the front of the aorta one-half an inch above its bifurcation."

At St. Thomas's there was found a movable right kidney with an artery from the aorta and one from each common iliac.

#### VEINS OF THE CAPSULE OF THE KIDNEY.<sup>8</sup>

Tudler and Lejars have done some very pretty work on the veins that surround the kidney. They find five groups: (1) Those forming a network over the kidney, which in some animals, as the seal, reaches an enormous development, but which in man is often overlooked. (2) Those of the peritoneum in the

<sup>6</sup> American Journal of the Medical Sciences, January, 1891.

<sup>7</sup> Journal of Anatomy and Physiology, vol. xxv, October, 1890.

<sup>8</sup> Archives de Physiol. Norm. et Path., 1891, No. 1.

neighborhood. The authors point out that Retzius had already shown that after tying the portal vein he found matter injected into the veins of the descending colon return by the left renal vein. (3) Veins about the supra-renal capsule connecting with those of the capsule of the kidney. (4) Capsulo-spermatic veins connected with the lower part of the capsule of the kidney and joining the system of the spermatic vein (we are not sure how this is on the right) and a fine plexus surrounding the ureter. (5) And lastly, there is the capsulo-lumbar system. It is evident that in case of temporary or permanent obliteration of the renal vein, the way for a collateral venous circulation is already prepared. The authors state that there is an arterial branch corresponding to each group of veins. For that matter Turner showed many years ago a subperitoneal system of anastomoses between minute arterial branches of the parietal and of the visceral systems.

#### THE MINUTE ANATOMY OF THE SPINAL CORD.

Professor von Kölliker<sup>9</sup> has written a paper on the minute structure of the cord and cerebellum, of which a translation and abstract has been made by Mr. William Alden Turner.<sup>10</sup> It seems that von Kölliker has, to a great extent, devoted himself to confirming the results of Golgi and of Ramón y Cajal. We shall present merely Mr. Turner's summary of the part of the work devoted to the spinal cord. A comparatively new and very important feature is the system of lateral offshoots from nerve fibres in their course through the cord called "collaterals" insisted upon by Golgi and alluded to in our last "Report on Anatomy." Here follows Mr. Turner's summary, which we think it advisable to give verbatim:

(1) The sensory root fibres divide at their entrance into the cord into an ascending and descending branch.

(2) Some of these sensory fibres course for a considerable distance (4-6 cm.) longitudinally; others arch into the gray matter, and end free in delicate ramifications.

(3) An association between the sensory root fibres and the cells of the gray matter of the cord has not up to the present been observed.

(4) All sensory longitudinal column fibres give off delicate lateral branches—the so-called *collaterals* of Ramón y Cajal, which, entering the gray substance, ramify in all its parts and end free.

(5) The motor root fibres arise from greater and smaller nerve cells of the anterior horn in a single nerve process, which in certain cases (always, according to Golgi) give off lateral branches.

(6) The anterior and lateral columns consist partly of fibres, which are given off by nerve cells in all parts of the cord. These column fibre cells (*Strang-zellen*) give off from their axis-cylinder process a greater or less number of lateral branches into the gray substance, which end free.

(7) The relations of the nerve processes of the anterior and lateral column cells to the fibres in the white substance varies. In some cases they simply bend upwards and pass into a column fibre; at other times they divide into two or three branches; or, again, such a nerve process splits into an ascending and a descending fibre, or apparently attaches itself laterally to a column fibre (the T-shaped fibres).

(8) The great majority of the fibres of these columns give off collaterals, which enter the gray matter of the anterior horn and of the anterior part of the posterior horn, and there end free, just as the sensory collaterals do.

(9) The anterior and lateral column fibres bend in many cases at a right angle into the gray substance, and there end free.

(10) All collaterals of column fibres, and all lateral branches of axis-cylinder processes, end in the same way. They give off at acute or right angles a greater or less number of branches, and finally form delicate end bushes, which encircle nerve cells without associating themselves with them or forming any anastomoses.

(11) The anterior commissure consists of: (a) Axis-cylinder processes of nerve cells of the gray matter, which, after decussating, are continued as longitudinal fibres of the anterior and antero-lateral columns. (b) The decussating collaterals of the anterior and lateral columns. (c) The decussating protoplasmic processes of a part of the median cells of the anterior horn.

(12) The posterior commissure consists of: (a) The decussating collaterals of the sensory root fibres. (b) Possibly, of the decussation of the collaterals of the posterior part of the lateral columns. (c) Decussations of the axis-cylinder processes of cells placed laterally to the central canal and *substantia gelatinosa* (Ramón y Cajal). But this is very doubtful. (d) Decussations of the protoplasmic processes of cells of the posterior horns. This also is not quite ascertained.

(13) The nerve cells are divided into: (a) Motor cells (*vide* under 5). (b) Column cells (*vide* under 6). (c) Cells whose axis-cylinder process does not go beyond the gray matter, and forms delicate ramifications in this. These only exist in the posterior horn.

(14) The value of the size, shape and character of the nerve cells is not fully known. It is, at any rate, certain that large nerve cells are not limited to the motor sphere only.

(15) The protoplasmic processes of all nerve cells ramify over a great extent in all directions, often penetrate the white matter, give origin to no nerve fibres, and do not anastomose.

### Reports of Societies.

#### THE OBSTETRICAL SOCIETY OF BOSTON.

CHARLES W. TOWNSEND, M.D., SECRETARY.

MEETING, March 11, 1891.

DR. E. W. CUSHING read by invitation a paper entitled

#### VAGINAL HYSTERECTOMY FOR CANCER.<sup>1</sup>

DR. EDWARD REYNOLDS said that there were two points suggested to him by the paper which he wished to speak about, the first being that for purposes of diagnosis he had found that pieces cut out of the cervix with a large size Mixer punch were better than the slices obtained with the scissors. Secondly, if one can give even six months relief by this operation it is worth while performing it. A case which was in cachexia that he operated on a year ago is now active and useful.

<sup>1</sup> See page 517 of the Journal.

<sup>9</sup> Zeitschrift für Wissenschaftliche Zoologie.

<sup>10</sup> Journal of Anatomy and Physiology, vol. xxv, April, 1891.

DR. CONANT spoke of a case where scrapings from the cervix were examined by a pathologist and nothing abnormal found, while eight months later, the disease having progressed, the diagnosis from the scraping was easily made.

Owing to the very extensive lymphatic supply in the broad ligaments, and the strong possibility of the disease becoming established there, he believed it wrong to call a case cured until three or four years had elapsed after operation. He did not believe that one or two years was sufficient for this purpose.

In a case of continued cachexia coming on after the operation, the case finally coming to autopsy, cancer of the broad ligament was found.

DR. F. H. DAVENPORT said that in general he heartily agreed with the reader of the paper as to the advisability of performing total extirpation in all cases where the disease had not so invaded the broad ligaments as to render any radical operation futile. The only exception he would make was in those rare cases where the very beginnings of the disease on the cervical portion were observed, and there was a probability amounting almost to a surety that all of the disease could be removed. He had seen a few such cases. The two reasons why he would prefer high amputation were because he considered the operation in itself less dangerous than total extirpation, and because in case of return a second operation could be undertaken with greater show of success than after the more radical procedure. Dr. Cushing had spoken of one case where after high amputation the disease had returned in the broad ligament. In Dr. Davenport's experience the return had usually been in the stump, and a second or even a third scraping and cauterization had finally resulted in cure. After total extirpation the return of the disease admits of no secondary operation.

It was very rare, however, that cancer cases were seen at the beginning, and he had come to feel that with our uncertainty how far up the canal the disease had progressed, it was safer to do the more radical operation. A recent case had emphasized this. He had been asked to operate upon a case in an adjoining city which had been pronounced by a competent observer very suitable for the high amputation. The disease seemed to be confined to the cervix, and the cut surface of the large wedge-shaped piece which was removed seemed absolutely healthy, yet Dr. Whitney reported an extension of the disease along the uterine canal. As the broad ligaments were quite free from disease, the total extirpation would have been better.

Dr. Davenport had performed the operation five times. Two of his cases were alive more than a year after the operation, one died of a return of the disease in a few months, and two died from the immediate effects of the operation itself. One of these last cases was not suitable as the disease had invaded the broad ligament on one side, and also the anterior vaginal wall so that the bladder was unavoidably opened. She was in a very weak condition, and died on the fourth day from exhaustion. The other fatal case should have been saved. The operation was an easy one, all the disease apparently removed, and the patient's strength was still very good. But she never really rallied from the operation. Her temperature fluctuated between 99° and 102°, her pulse never fell below 120, and she died on the fifth day. Dr. Davenport could not satisfy himself that there was any septic process going on.

Even with this large mortality he would unquestionably perform this operation in preference to the high amputation where the disease of the cervix had got beyond the initial stage and the broad ligaments were free.

DR. A. H. JOHNSON, of Salem, wished to emphasize the point Dr. Davenport had made of the significance of menorrhoea after the menopause. He had recently made an autopsy on a woman seventy-three years of age dying of intestinal trouble, no uterine symptoms having existed. The uterus was much atrophied, but contained a polypus the size of a walnut. The absence of hæmorrhage he believed was due to the senile atrophy and the insufficient blood-supply.

DR. BLAKE had had the privilege of seeing the operation done many times, and agreed with the reader that this was the operation which gives the best chance for cure. Microscopic examinations of specimens from the cervix could not tell us of the condition of the fundus, and the high amputation of the cervix might still leave some of the growth behind. The fact, that none of the patients on whom the operation of vaginal hysterectomy was performed, reported in the article by Lusk in the "American System of Gynecology," were living at the end of five years, might be explained by the fact that only hopeless cases were treated in this way. It was certainly a boon to both patient and physician to get rid of the bleeding, discharging uterus.

DR. CUSHING in closing, said that he had operated on a case to-day where externally there was nothing apparent but a small bleeding point, but inside was a broken-down carcinomatous nodule. Here the punch Dr. Reynolds spoke of might be of good service. In three of the cases reported he did a partial operation first by preference, in order to check the hæmorrhage and give the patient a chance to recuperate. Later, the total operation was easily done.

He did not claim that the total operation was a cure in these cases reported, for some or all may recur, the first case having been operated on a little less than four years ago; but he does claim that it gives entire relief for a longer or shorter period at least, and that the patient is able to be up and about.

He prefers it to the high operation which is about as difficult and as dangerous as the total operation. Schroeder lost some eight per cent. of the cases of high operation. Besides this one cannot tell how high up the disease goes, hence it is wiser to remove the whole organ. At the *Frauen Clinic* in Berlin, the high operation is still done in favorable cases with a recurrence in forty-five per cent., but total extirpation is practised among the more severe cases.

In order not to bring discredit on the operation, and thus deter suitable cases from resorting to it, he believed it unwise to operate where it was perfectly sure that the disease would soon recur.

DR. W. M. CONANT read, by invitation, a paper on

#### THE CYSTS OF THE LABIUM.<sup>2</sup>

DR. HAVEN had in some cases followed the plan of dissecting the cyst out, but in others had opened, everted and packed without causing much discomfort or leaving a painful cicatrix and without any return.

<sup>2</sup> See page 519 of the Journal.

DR. DAVENPORT reported briefly a case seen by him in consultation, which presented some points of interest, and where the diagnosis was somewhat doubtful.

Mrs. M., age forty-one, had had six children and two miscarriages, the latter artificially produced as her medical attendant thought. She menstruated last, September 30, 1890. October 28th she began to vomit, and this was very persistent and severe until November 10th, when she had a very bad chill, followed by others that day and the next. On the 11th she began to have pains, and to flow somewhat. A careful examination of the clots failed to disclose anything like a foetus (as would be expected at this early period). Her physician's attention was called at this time to the swollen condition of the nasal mucous membrane, making it difficult for her to breathe through her nose. The history for the next twelve days was constant vomiting, a watery discharge slightly bloody from the vagina, becoming somewhat offensive in a few days, and then ceasing altogether. Some considerable nose-bleed; temperature normal or subnormal 96.5°-98°; pulse 60-70. There was no tympanites, no cough, no rose spots, no diarrhoea. All ordinary means were employed to stop the vomiting, including rectal feeding for several days, but were of no avail.

November 24th bleeding from the vagina began, and two days later her physician feeling confident that there were retained products of conception in the uterus, called me to see her with an idea of emptying the uterus. I found her in bed, lying on her side, breathing quietly. She was thoroughly etherized, and placed upon the side. A small amount of blood in the vagina was wiped away, and the cervix was moderately dilated with Hank's dilators. The tissues yielded very readily. The sharp eurette was then used, and brought away a teaspoonful of granular looking matter, white in color, and very friable. There was no odor of sloughing. The uterine walls were left smooth and clean and the cavity carefully swabbed with corrosive sublimate solution, and the vagina was tightly packed with corrosive sublimate cotton.

This operation had no effect on the vomiting. Bleeding became general from all the mucous surfaces, nose, gums, mouth, throat, vagina, rectum and umbilicus, and the odor from the body made it almost impossible to stay near her. She died November 29th. Her doctor's opinion which was shared by me, was that it was a case of septic absorption, but it certainly had unusual symptoms. The general hemorrhagic condition was a very strange feature as was the persistent low temperature.

DR. BOARDMAN said he had once observed a case of bleeding from various mucous membranes due to the cachexia following continual vomiting, although the present case did not seem to be of that nature.

DR. A. H. JOHNSON remarked that we were sometimes thrown off the track by observing one organ. For example, he had once seen a case where vomiting occurred in the early months of pregnancy, subsided, but returned again obstinately at the seventh month. Labor was finally induced in the belief that the pregnant uterus was the source of the trouble, but the vomiting continued until a gall-stone the size of a walnut was finally vomited. There had been no previous history or symptoms pointing to gall-

stones in this case. In the case under discussion it would seem to him as if there were some underlying cachexia as the cause of these hemorrhages, rather than any local cause in the uterus.

#### THE GYNECOLOGICAL SOCIETY OF CHICAGO.

REGULAR Meeting, December 19, 1890, the President, DR. W. W. JAGGARD, in the chair.

##### EXHIBITION OF SPECIMENS.

DR. C. T. PARKES showed a

##### POLYPOID MYOMA

removed from the vagina of a patient about fifty years old. He said: Upon examination I found the pelvis blocked with this tumor, which was showing signs of degeneration. It had been mistaken for a carcinoma on account of the foul discharge. I could get no history of the time when this polypus was discharged from the uterus, and no history of any severe bleeding of any kind; but upon anesthetizing her I soon found that it was continuous with a long pedicle attached to the anterior wall of the uterus, and so at one time in its history it was simply a small submucous fibroid. After separation of its pedicle with long curved scissors, it was delivered with considerable difficulty owing to its size, but without much damage to the vagina.

Dr. Parkes also showed a

##### PREGNANT UTERUS WITH FIBROID TUMOR.

It is a pregnant fibroid uterus of about four and a half or five months. At the time of the operation the mass filled the abdomen as full as pregnancy at full term. The patient had been two weeks in bed suffering great and continuous pain, showing a high temperature, considerable peritonitis, and trouble of different kinds, so that some interference was evidently necessary. The larger mass lay up under the liver, and here the most pain was felt. The smaller tumor was all we could feel in the pelvis, except by very forcible pressure of the finger where the cervix could be touched. The pedicle could be felt coming out of the cervix, and at the time of the operation it was found attached high up on the anterior wall. Examination showed pregnancy, and we deemed it advisable to make an abdominal section to remove the mass. The operation was done, the pedicle being treated by the extraperitoneal method. The patient went home entirely well in four weeks.

##### TUBAL PREGNANCY WITH TWO OVA IN THE SAME FALLOPIAN TUBE.

DR. CHRISTIAN FENGER showed a specimen of tubal pregnancy in the second month. The rupture of the sac occurred toward the end of the second month, causing considerable hemorrhage into the peritoneal cavity, so much so that the patient was exsanguinated. The rupture took place about four o'clock in the morning, and at nine o'clock we decided upon immediate operation. The woman was almost pulseless, and showed all the signs of dangerous hemorrhage. The operation was done at eleven o'clock. When the peritoneum was opened a great amount of liquid and large clots of blood were taken out, probably about three to four pounds in all. On digital exploration of the organs of the smaller pelvis, I felt a tumor on the left

side of the uterus, and by lifting the broad ligament out of the abdominal wound I got the whole tubal pregnancy, with the foetus hanging out of the ovum with the umbilical cord. During this manipulation I found in my hand an oval body which I present here. The patient recovered after an uninterrupted convalescence.

The specimen shows two ova, both located in the same tube. The degenerated or oval one is a cyst one and one-quarter by one inch in diameter, with a wall three to four millimetres thick. One-half of the ovum is covered with tubal wall; the other half, as will be seen in the specimen, naked. It contains a clear, gelatinous fluid surrounded by a transparent membrane covering the inside of the wall. This oval ovum is smooth on one-half of its surface; the smooth half being the thin wall of the tube which is adherent to it and has been broken off. The other half of the ovum has been included in the tube, and has been in connection with the walls of the tube or with coagula. The second ovum is ruptured and contains the foetus attached by the umbilical cord to the inside of the ovum, through the opening of which it protrudes. The foetus is between six and eight weeks old. This ruptured ovum is located in the abdominal half of the tube, and shows a smooth surface, to the upper part of which the umbilical cord is attached, and the outer surface of which is all covered with chorionic villi. Over part of the top is a smooth surface with ragged edges in the shape of a cap, which is a broken-off portion of the wall of the Fallopian tube. The two ova are close together, the one which had undergone cystic degeneration on the uterine side of the ruptured one.

The attending physician said that a year ago he suspected this patient of having had a ruptured tubal pregnancy. Whether the ova or degenerated ovum belongs to that period, a year ago, or is a twin ovum two months old, is, of course, an open question.

DR. ADDISON H. FOSTER reported

#### A CASE OF HEMICEPHALUS WITH HYDRAMNION.

Mrs. M., age forty, had a tedious and severe labor fourteen and a half years ago, from which she recovered fully, and went through a very normal labor one and a half years later. Eleven years ago she had twins at eight months that lived a few hours. Distention of the uterus seemed to be the cause of the premature labor. Her recovery was slow from this confinement, she being weak and very nervous. Subinvolution and extensive erosion of the cervix were found, which rapidly improved under local treatment, and with full recovery in her general health and spirits. Several years ago she had a normal though rather rapid labor and a strong, healthy child. Two years later she had a six months' miscarriage. Three years ago, with loss of flesh and strength, she grew very nervous and perverted in mind, which condition had not entirely disappeared. In March last she became pregnant, and improved in health and spirits from the first. In the last of August, or late in the fifth month, she began to increase in size more rapidly than is usual, so that by the seventh month she was fully as large as ever before at term. She was feeling very well all the while, going out to walk every day. Her only discomfort was weight and pressure, and the last three days before confinement she had a feeling "as if she was going to be sick." She feared twins, but, from rotundity of abdomen and fluctuation, she was

disabused of that idea, though she was not told our conclusion.

October 10th she began to have "slow, pressing pains" (as she termed them). Because of the great amount of amniotic fluid in the sac no presenting part could be distinguished. After full dilatation the membranes were punctured as high as possible anteriorly during an interval of pains, when at least two gallons of fluid escaped, deluging the bed, mattress and floor. The presenting part was anomalous to me, when a few strong pains suddenly expelled a hemicephalus dead foetus of about seven months' development. The shoulders presented, and not the breech as is often the case. The mother made a prompt and good recovery, and is in a better condition of body and mind than she has been for two years. An excessive amount of amniotic fluid, while supposed to result from various causes — maternal, foetal, or both — is an almost constant factor in cases of monstrosity.

DR. W. W. JAGGARD: The case of hemicephalus is a typical example of cranio-rhachischisis. According to the old view — Morgagni, Förster — cranio-rhachischisis is due to hydrops caualis cerebro-spinalis at an early period of fetal life. Fluid collects in the embryonal cavities of the brain and spinal cord until the sac ruptures outward. The development of the bony covering is thus prevented, and the uncovered basis of the ventricle is exposed to the action of the liquor amnii. Dareste and Perls ascribe the malformation to a pressure from without upon the vertex and back of the neck. This pressure, according to Dareste, is present when the amniotic cap of the head-fold of the embryo fits too tightly at a time when the cranial vault and spinal canal is still covered only by skin. Ahlfeld effects a compromise between the old and the new views, while Lebedeff is of the opinion that very early in embryonal life a medullary tube is either defectively formed or the posterior wall is destroyed.

These individuals are not viable. From an obstetrical point of view, the anomaly is of interest from its association with hydramnion, when the defective portions of the brain and spinal cord are not covered by epidermis. According to Fritsch, the excess of liquor amnii is due to the outpouring of cerebro-spinal fluid after rupture of the hydrocephalus or of the hydrorhachis. According to Lebedeff the secretion comes from the ependyma.

Hemicephali commonly present by the head, and seldom cause dystocia, except when the shoulders are unusually broad.

#### LAPAROTOMY FOR EXTRA-UTERINE PREGNANCY TWO MONTHS AFTER DEATH OF FŒTUS AT TERM.

DR. C. T. PARKES showed the entire sac and foetus removed from a case of extra-uterine pregnancy two months after the child's death at term. The child was macerated and showed marked evidence of decomposition. The sac was rotten and easily broken, especially at the upper and thinnest portion. A portion of the sac was within the pelvis, and a higher portion, which was very thin, extended upward to the highest point of the mass. The uterus was carried to the left side and out of the pelvis, where it could be easily felt before the operation. The intention on commencing the operation was to open the sac only, remove contents, and sew edges of opening to the abdominal incision; but accidental rupture of the upper, rotten portion rendered complete removal necessary.

The patient had been married seven years, but this was the first pregnancy. Last menstruation in June. The first suspicion of an abnormal condition of pregnancy was in March, when for several days unusual pains were felt, supposed to be premonitory of labor. When these pains subsided, the fetus was found to be dead. March 28th the decidua membrane was passed entire.

From then until the last week in April there was progressive diminution in the size of the abdomen, showing absorption of amniotic fluid, flattening of the breasts, and an apparent general improvement in the patient's general health, as indicated by increase of flesh and strength and better color; she at times rode out, and walked for many blocks without suffering pain or becoming fatigued.

In the last week in April there were severe abdominal pains, neuralgic and cramp-like in character; fever appeared; the pulse became more rapid; there was loss of flesh and color; in short, septic trouble commenced.

The abdomen presented two distinct enlargements: a greater occupying nearly the entire abdominal region, but situated slightly to the right of the median line, most prominent just to the right of the umbilicus, and extending to the height of normal pregnancy at term; a smaller, simply a projection, about the size of the closed hand, lying in the left lumbar-regions, freely movable and the seat of frequent pain. The former was plainly the fetal tumor; the latter probably the enlarged uterus displaced.

The os uteri was with great difficulty detected, and was found behind the pubic bones, soft and dilatable, but at the time of the passage of the decidua membrane the examining finger readily entered the os, passed upward, forward and decidedly to the left. The cervix and body of the uterus were found empty.

Directly posterior to the os uteri, and occupying the cul-de-sac of Douglas, the fetal head could readily be made out, the sutures being very plain.

A peculiar condition in this case was the almost total obliteration of the vaginal portion of the cervix, causing the pelvic tumor to appear like a normally pregnant uterus, so much so that a consulting physician declared, as late as April 25th, that the child was dead in the uterus.

The immediate reasons for operation were principally evidences of general septic infection, chills, sweatings, diarrhoea and high temperature. The operation was done May 9th.

The tumor was of a dirty sphacelated appearance, soft and easily broken down. It was incised, and out of the opening there was discharged an offensive, thick fluid in considerable quantity. The child was seen at once, breech upward. The legs were seized and the child quite easily delivered, but during its delivery the thin upper portion of the sac was torn, allowing the small intestines to protrude into the sac and the fluid contents of the sac to enter the abdominal cavity. It was, therefore, thought best to remove the entire sac, if it could be done.

The tumor seemed to be covered on all surfaces with peritoneum. The caecum on the right and the sigmoid flexure on the left were intimately adherent to its walls.

At a critical moment the light in the room was made poor by a storm outside, and this led to a separation of a portion of the sigmoid flexure too close to its

walls, so far interfering with its vitality that a small portion of it sloughed away on the sixth day. The right ureter failed also to be recognized, and was included in the grasp of one of the forceps and divided. Neither of these accidents would have happened had the light been even fair.

Upon removing the dressings on the sixth day fecal matter was found in the wound.

The progress of the case was favorable in every way, except the fecal fistula, until the eleventh day, when the patient began to show signs of obstruction of the bowels. Persistent and uncontrollable vomiting commenced. There was neither discharge of gas or feces from the wound nor from the rectum. The patient became rapidly and profoundly exhausted, and died on the twelfth day after the operation.

The post-mortem showed an opening, about the size of half a dollar, in the lowest part of the sigmoid flexure. Several folds of intestine were constricted in an opening in the remnant of the sac wall. The kidney on the right side was noticeably atrophied. There was no evidence whatever of peritonitis.

REGULAR Meeting, January 16, 1891, the President, DR. W. W. JAGGARD, in the chair.

DR. L. L. MCARTHUR read a paper on

#### CANCER OF THE RECTUM.

After quoting from several authorities on the subject, the author said: I would urge that prior to every excision in every painful case, and in every case where the disease was situated high up, that a colostomy be made, the choice being in favor of the left inguinal. The method of excision recommended by the French surgeons has been that which I have utilized, preceding each excision, however, by a colostomy two or three weeks prior to the final operation. In this the main feature is a deep incision which exposes the posterior segment of the rectum from the anus to the coccyx, when it is an easy matter to dissect out the rectal tube until one comes to the anterior portion. Here, if it is found that the disease involves one or more of the coats of the vaginal wall it is best to remove a longitudinal segment of the entire thickness of the same, as it both renders the operation safer and more easily accomplished, and does not, as Kelsey would infer, greatly increase the danger. When the sphincters are involved a circular incision should surround the anal opening, and all be removed together. Dr. Guerin's suggestion that the gut be cut through by the *écraseur*, modified by the passing through the normal gut of several threads for purposes of fixation of the proximal end after removal, as recommended by Verneuil, has been the procedure employed in the excisions I have made. The proximal end is then to be stitched to the posterior angle of the perineal incision or to the left side of the coccyx, and, after stitching up the vaginal wound in much the same way as after a posterior colporrhaphy or laceration, deep transverse perineal stitches render the making of a new and extensive perineal body easy.

When the type of the disease is that of the cauliflower-like growth known as papillo-carcinoma, the best practice is to remove it with the *curette* rapidly and well down to the base of the growth. The hamorrhage, very active and easily provoked while in the soft tissues of the tumor, is easily controlled when the base has been reached. In two such cases I have been successful in for a time relieving them of their distress-

ing symptoms, but have not been able to follow their history for more than six months after operation.

The case I report is of interest in showing the benefit to be derived from surgical interference.

**CASE.** After having suffered with what she believed to be hæmorrhage, the patient came to St. Luke's Hospital a year and a half ago, with symptoms of absolute stenosis of the intestine, and requiring immediate relief. The diagnosis of carcinomatous obstruction of the rectum being made, a colostomy in the left lumbar region was done, with relief to the urgent symptoms. After the lapse of three weeks, the artificial anus being well established and healed, an excision of the rectum was practised after the usual methods by a deep posterior incision from the anus to the left side of the coccyx well down to the posterior wall of the rectum, which was then dissected laterally until the vaginal wall was reached, which was found to be involved to the level of the posterior lip of the cervix in the carcinomatous growth. The posterior wall of the vagina was removed, as well as the rectum, to this level, including the sphincter muscles. The rectum was stitched to the skin of the left side of the coccyx, and deep transverse stitches were inserted to make a new perineal body. There was speedy union and rapid convalescence. After the lapse of one year she returned to me with the artificial anus presenting a normal rectal mucous membrane normally attached to the integument to the left side of the tip of the coccyx, with the artificial anus almost closed from surgical interference, but with a return in the perirectal tissue of the original trouble to such an extent that the line of cicatrix in the vaginal wall posteriorly and in the anterior rectal wall was again invaded by the new growth, which was beginning to cause painful defecation as at first. The patient requested a repetition of the operation. This at first I refused to make, but finally I excised the portion of the rectum which had been drawn down and attached to the integument, at a point on a level with the posterior lip of the cervix. I dissected out laterally, in so far as I could reach, all indurated tissue. I then found that it was impossible to bring the end of the rectum down to the integument, no matter how far I might extend my posterior incision, and decided that the best thing I could do would be to suture the end of the rectum at the top of the vaginal incision after the cicatrix had been removed. I did this, then united the vaginal mucous membrane, much as is done for a laceration or operation for posterior colpoperforaphy, and brought the lateral pelvic tissues together by very deep, heavy silk sutures, and, strangely enough, obtained a perfect union. The patient has, since the second week in November, been at home, is feeling well, has gained in weight, and has several times come to my office, each time stating that she feels better than she did during the year which elapsed after the first operation, that she now has control of the bowel and is capable of evacuating its contents without any artificial assistance—that is, without a douche, which I advised when she first left the hospital.

I believe this to be a unique case. I do not find in what literature I possess, reference to a similar operation. I have no doubt that she will ultimately have a return of the trouble, because the cicatricial contraction which normally occurs with any inflammatory deposit about the rectum, whether from specific or simple inflammations, has already produced some suspicious induration.

**DR. C. T. PARKES:** We must look upon this operation for the relief of this terrible disease mainly as a palliative treatment; it is seldom curative. Certainly it removes the manifestations of the disease for a time, and, above all, is desirable, from the fact that it relieves the patient from the local distress caused by the disease, especially from pain, which is present in all these cases, and the symptoms of on-coming obstruction which accompany the later stages. I recall nine cases in which operation has been done for excision of the rectum, two cases in which simple incision was done, and two cases which are interesting from the fact that they accompanied the presence of ovarian tumors, and one case which was situated very high in the rectum and no interference was practised—in all fourteen. Of the nine cases in which excision was done, five were operated upon according to the plan of Kraske; in the others success was attained in the removal of the manifestations of the disease by merely external incision of the soft parts, without interference with the sacrum or coccyx. Of these cases, which represent a period of work of eight or ten years, some are living to-day, but most of them are dead. None of the cases of excision were preceded by an opening into the colon. I think the statistics which the reader gives as to the mortality of the disease as the result of immediate excision is based upon the results of pre-antiseptic days rather than the present. I am not one of those who believe that the contact of faecal matter with the wound is at all times hurtful, as I have had in my experience many cases in which wounds have been bathed in faecal matter without any septic condition following. I can see readily enough that the previous operation for an artificial anus can be a benefit to these cases, and will likely predispose to the earlier and more rapid healing of the rectal wound, simply because it prevents the faecal material from passing over the raw surface. The operation of forming an artificial anus in itself is of little consequence, and should be, as a rule, attended with little fatality. That it is a necessary procedure, I am not inclined to believe; neither do I think that it makes very much difference in the mortality. The disposition is in all these cases to a comparatively rapid return of the disease. We must always remember, in the treatment of cancer here as well as elsewhere, that the operation itself may stimulate or produce infection. In two cases in which the operation was done by myself, there followed no local manifestations of return of the disease, but within eighteen months there appeared to be general infection of the entire body. There is no question but that every one of these patients will be grateful to the surgeon for the removal of the manifestations of this disease. A number of surgeons of great experience, believe that the establishment of an artificial anus itself is a sufficient relief to the case. Other operations are done besides excision of the rectum, which is a formidable operation and leaves disgusting results in many cases. For instance, the complete division of the mass backward towards the sacrum, in that way providing for the easy exit of the fecal matter.

**DR. HENRY T. BYFORD:** I would like to emphasize what Dr. Parkes has said, that this is a palliative operation and not justifiable when it is immediately very dangerous to the life of the patient. The case related is similar to a case which I have treated, and which illustrates the principle which should be carried

out in treating cancer of the rectum in women. The sphincter was not involved, although the rectum from about two and a half inches above, down nearly to the sphincter was affected on its anterior and lateral aspect. I removed portions of the lateral and anterior rectal walls, and the posterior vaginal wall. Instead of drawing the parts together in front of the rectum, I operated upon the principle that all raw tissue not covered by mucous membrane will contract and obliterate the entire tract within it; so I endeavored to secure as large a surface of mucous membrane for the canal as possible by leaving the vagina open and merely closing up the vaginal entrance. There is another reason for removing in cancer of the rectum, all of the rectum that we can, namely, that a return of the disease in connective tissue is not as painful as when it attacks the viscera. In this case the patient was able to evacuate the bowels until the entire pelvis was filled up with a mass of carcinomatous tissue, without very much pain. She died finally of exhaustion more than anything else. The point in all these cases is to get as much mucous membrane as possible, using the vagina the same as in any other operation.

DR. L. L. McARTHUR, in closing the discussion, said: In presenting the patient this evening I did not do so to advocate such an operation, although in cases in the female in which carcinoma occurs low down in the rectum, in reality it would be a procedure more advisable than to make an artificial anus at one side of the tip of the coecum, because of the statement of the patient that she knew when the bowels desired to move. She had a peculiar feeling, she says, and has the power to expel the contents, thus escaping the exceedingly distressing symptoms of involuntary discharges, which always occur with an artificial anus at other points.

### Recent Literature.

*A Treatise on the Diseases of Infancy and Childhood.* By J. LEWIS SMITH, M.D., Clinical Professor of Diseases of Children, Bellevue Hospital Medical College; Physician to Charity Hospital, etc. Seventh edition, thoroughly revised, with fifty-one illustrations. Philadelphia: Lea Brothers & Co. 1890.

This valuable book has been so long before the profession and is so well known from the care with which it has been revised and kept abreast of the times, that little need be said, beyond again commending it to those interested in pediatrics and general medicine. In the seventh edition, as new articles, are the following subjects: hæmatemesis, icterus, sclerema, œdema, pemphigus, appendicitis, typhilitis and perityphilitis. Also, a paper on Intubation by Dr. Joseph O'Dwyer.

*A Treatise on the Diseases of the Nervous System.* By WILLIAM A. HAMMOND, M.D. With the collaboration of GRAEME M. HAMMOND, M.D. Ninth Edition, with corrections and additions. 8vo, pp. 932, with 118 illustrations. New York: D. Appleton & Co. 1891.

The present edition has been revised, and a few new chapters have been added, notably chapters on acromegaly and syringomyelia. In the revision certain of the grosser errors of the eighth edition have been corrected. The work, however, is still distinctly unworthy of the favor it has enjoyed.

## THE BOSTON Medical and Surgical Journal.

THURSDAY, JUNE 4, 1891.

*A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.*

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DANRELL & UPHAM,  
283 WASHINGTON STREET, BOSTON, MASS.

### THE STUDY OF STATISTICS.

THE student of medicine, as well as the busy practitioner, is apt to value too lightly the importance of the study of vital statistics, and of contributing, each one his quota, to the general fund of information. Very much of his accurate knowledge in regard to the prevalence of diseases, their fatality at different ages of life, and their prognosis, depends mainly upon the faithfulness with which his brother practitioners have made these things a matter of careful record and registration.

Such books as the Registrar-General's Reports of England, the Confronti Internazionale of Professor Bodio, the publications of the Gesundheitsamt of Germany, may contain a vast amount of dry and uninteresting statistical material, but are nevertheless works of the highest importance as aids to medical science.

In a recent work<sup>1</sup> upon this subject, Longstaff says: "The numerous and voluminous reports on the very dusty shelves of the library of the Statistical Department of the General Register Office, form a vast reservoir, into which a ceaseless stream of facts has been flowing for more than half a century. To disturb the dust upon those shelves; to fish out facts; to group, arrange, compare, and ponder over them has long been my hobby."

That the author has made a successful use of the vast multitude of facts which he has examined, is evident from the valuable volume entitled "Studies of Statistics," in which he has arranged and classified a great deal of material from the Census Reports of different countries, not excepting the ponderous tomes of the United States Census. From these he draws deductions and inferences relating to the rapid growth of urban populations, the effects of migration, the growth of new nations, the food supply, and certain statistical inquiries relating to infectious diseases.

The fact that England and Wales increase in population at the rate of 1,000 per day, and London at the

<sup>1</sup> *Studies in Statistics: Social, Political and Medical*, by George Blundell Longstaff, M.A., M.B., etc. With maps and diagrams. London: Edward Stanford, 1891.

rate of 150 per day, is not so important as the fact of the marvellous general increase of the population in the present century. In the Colonies and in the United States, villages have become towns, and handfuls of pioneers have grown into nations. "Nations which, while supplanting the picturesque, if filthy customs of the savage, by the healthy, but hopelessly unpicturesque civilization of Europe, are gradually but surely changing the centre of gravity of the political world."

Those who look with considerable anxiety upon the great increase of the human race in relation to the food supply of the earth, will find their gloomy anticipations to some extent supported by Dr. Longstaff, who, in the chapter on the food supply, concludes that "it is no exaggeration to say that the time will come, and that before the end of the next century, when men will once more think seriously of Malthus and his warnings." He lays emphasis on the fact that the demand for food increases every year, not merely in Europe, but even more rapidly in those countries which we are too apt to regard as merely the granaries of Europe.

The last chapters of the work, comprising about half the volume, are of especial interest to medical men. These treat of "the decline in the death-rate considered in connection with the causes of death," "the causation of summer diarrhoea," "some indications of a relationship between scarlatina, erysipelas and puerperal fever," "the distribution of diphtheria in England and Wales," "phthisis, bronchitis and pneumonia," "the communicability of phthisis," "constitutional fevers in London," and "hydrophobia."

He attributes the decline in the death-rate from 22.3 per 1,000 in the early period (1838-1875) to 20.3 in the later period (1876-1883) to a diminished number of deaths assigned to fever, phthisis, scarlet fever, diarrhoeal diseases, small-pox, diphtheria and measles. There was also an increase in the same period in deaths from cancer and diseases of the heart, lungs and kidneys. In this connection he suggests that preventive medicine should be directed especially against those diseases which kill the largest numbers, such as "local diseases," the ill-defined diseases of infancy, and phthisis, and among the "zymotic" diseases, diarrhoea, scarlet fever, whooping-cough and measles. He shows that while density of population has undoubtedly increased, the increased attention paid to hygienic matters by the individual, the corporation, and the State, has more than counterbalanced the evils attendant upon such increase of density.

The chapter on the distribution of diphtheria has peculiar interest to our own country, where diphtheria is still more prevalent than in Great Britain. He shows that for the twenty-five years (1855-1880), taking into account the disparity in numbers of the sexes, about seven per cent. more females died from this cause than males.

With reference to its geographical distribution he shows that density of population is not a prime factor,

but that the disease has a strong predilection for rural populations, the districts of Lincoln, Norfolk, Sussex and North York having the highest death-rates from this cause, and these all have comparatively sparse populations. Assuming the mortality of dense districts as 1,000, the comparative figures were as follows: mortality from diphtheria in dense districts, 1,000; in medium districts, 1,178; and in sparse districts, 1,507.

With reference to the disputed question of causes, Dr. Longstaff goes on to say "the cause or causes should not be sought for primarily in any high development of civilization, such as sewers, but rather in some condition associated with more primitive modes of life. Again, privies and ash-pits can hardly be important agents in breeding, or disseminating the disease, or we should expect to find diphtheria exceptionally prevalent in those northern towns where such nuisances reach their worst, whereas the contrary is the case. On the other hand, low vegetable organisms developed in damp dwellings would perhaps fit in with the facts that I have brought forward; or again, some evil special to shallow wells, or other primitive sources of water-supply. The line of investigation, however, which seems to me most promising, lies in comparative pathology. The peasantry live on intimate terms with domestic animals, more particularly cows, sheep, pigs and poultry, (including pigeons). Some little known disease of some one or other of these creatures may be capable of inducing in men or women, brought into frequent or close contact with them a trivial 'membranous sore throat'; then under suitable conditions of recipient and environment, the more generally recognized form of the disease, 'true diphtheria,' or, as it used to be called, 'cynanche maligna,' may result. The poison, perhaps gathering intensity and infectiveness, may then be conveyed into towns by farm produce, such as milk, cream or poultry, conceivably by eggs, meat or vegetables; and lastly, through the persons first infected, the sources of water-supply or the public sewers may get poisoned, and so indirectly, aid in the spread of the disease."

The relations of phthisis, bronchitis and pneumonia are considered in one chapter; and in this inquiry Dr. Longstaff finds valuable aid in the work of Drs. Buchan and Mitchell upon the relations of disease to meteorology. As a result of this investigation he makes the following propositions — not, however, as direct conclusions, but for the purpose of awakening interest and discussion:

(1) The mortality statistics of England and Wales throw no light upon the question of the communicability of phthisis, but the evidence, so far as it goes, is negative.

(2) Cold weather has but very little influence upon the phthisis death-rate.

(3) The bronchitis death-rate is greatly affected by temperature; that of pneumonia also, but not so markedly.

(4) It is difficult to explain, by meteorological phe-

nomena only, all the fluctuations of the mortality from bronchitis and pneumonia.

(5) No support is given to the theory of pneumonia being a disease allied to typhoid fever.

(6) Although the facts do not exclude the possibility of a communicable pneumonia, having no connection with cold, they show that such a theory can account for but a very small proportion of the deaths attributed to pneumonia.

(7) While the mortality from pneumonia, and more especially from bronchitis, appears to be mainly regulated by intense cold, by fogs, and the cold winds of early spring, the occasional want of correspondence between the assumed causes, and the alleged effects suggests that possibly bronchitis and pneumonia, or many of the cases so designated, may be communicable, or they may be complications of a communicable disease, more or less fatal, according to the prevailing meteorological conditions.

(8) Many domestic incidents suggest that common catarrh, or some form of it, is more or less communicable. Is this communicable catarrh, assuming it to exist, a mild form of influenza? and are many cases of bronchitis and pneumonia to be regarded as serious complications or sequelae of that neglected but most troublesome ailment?

(9) The fact that whereas, in equal numbers living, 1,103 males die from bronchitis to every 1,000 females, but as many as 1,460 males die from pneumonia to every 1,000 females, suggests that the two diseases have different causes.

(10) The curves suggest a common factor in the two diseases, phthisis and tubercular meningitis.

The chapter on the communicability of phthisis is an attempt to answer the question as to the probability of the accidental and fatal incidence of phthisis upon husband and wife, the problem being stated as follows:

"Required to find in how many cases in England and Wales, during the decade 1871-80, both husband and wife would die of phthisis, assuming the chances for married and single to be equal in all respects."

The problem is worked out upon a purely mathematical basis, with the result that "during the ten years, 1871-80, in England and Wales, assuming marriage to have no influence upon phthisis by selection, infection or otherwise, it would happen 4,363 times that both husband and wife would die of that disease." The author, therefore, concludes that, to show any substantial argument for the existence of infection, it would require a much larger collection of cases than has yet been published.

The chapter on hydrophobia was written in consequence of an increased prevalence of this disease in 1885. The deaths from this cause for the period 1847-1885 in England and Wales were 944. These were very unequally distributed from one death in 1862 to a maximum of 79 deaths in 1877. The deaths in London from the same cause for forty years were 145. With reference to seasons of the year, the month of September showed the greatest fatality, and March

the least. Four-fifths of the deaths were of males, and one-fifth females. There were 124 deaths of children under five, 323 from five to 15 years, and 528 between 15 and 65 years. Stress is laid upon the fact that young children are less completely clothed than adults, and less able to defend themselves. The geographical distribution of the disease shows remarkable features, Lancashire having by far the greatest number of deaths from this cause, 225; West York, 100. There were none in Huntingdon and Westmoreland. Occupation appears to have had but little influence upon it.

In conclusion the author states that one of his principal objects in publishing this excellent volume has been "to indicate to medical writers the vast mine of material existent in the voluminous returns of the Registrar-General—material of which the great majority of the medical profession seem to be still ignorant, although it is plainly desirable that every hypothesis put forward by searchers after the causes of disease should be tried by the touchstone of this mass of crystallized experience."

The book is finely illustrated with numerous diagrams and colored maps.

#### STATE REGULATION OF THE PRACTICE OF MEDICINE IN PENNSYLVANIA.

AMONG the State legislatures which have discussed bills regulating the practice of medicine this year, is that of Pennsylvania, which already has a Registry Law. As this was found insufficient to drive incompetent practitioners beyond the State border, a bill was introduced providing for a board of examiners. This bill was not all that could be desired, but feeling that it was better than none, it was approved by representative medical men.

On the other hand, the opponents of the bill, also including men well known in the profession, drew up a circular embodying their objections to it, and the legislature, apparently not being able to decide the relative merits of the arguments, adjourned without taking action on the subject.

The opponents argued that to establish a State Board of Examiners, according to the proposed law, would tend to lower the standard of medical education, since by the wording of the bill the governor was not allowed to appoint members of the medical faculties on the Board, thus excluding the men most capable of acting as examiners. Again, since the Board was to be paid by the number of men that they passed, a temptation would be offered to pass as many as possible, a very palpable objection to the bill. The bill provided that no one should be rejected on account of adhering to any special system or school of medicine; and consequently it would be necessary to appoint on such a Board representatives of all sorts of medical or pseudo-medical fraternities, the effect of which would be to make it incompatible and incongruous. Also, in connection with the clause which allows the candidate to choose the system of *materia medica* and therapeu-

ties in which he or she shall be examined, the circular says: "The eminent defectiveness of this section is painfully apparent. Our experience enables us to claim with emphasis that no option should be allowable in an examination upon the prescribing of powerful and poisonous drugs."

Each applicant is by the proposed law obliged to pay twenty dollars for a license to practice, a charge which seems oppressive in view of the fact that he has already been obliged to pay a fee for his diploma, which is supposed to carry the right to practice with it, and which is given by the medical college under a charter allowing such degrees to be issued. The proposed law requires the faculties of medicine to give diplomas after examination, and then calls in question, or even renders valueless, the value of the diplomas by requiring subsequent examination.

Pennsylvania has already a law making the registration of a diploma necessary to obtain a license to practise. This would seem to imply that a diploma carried with it a legal right to practise, especially if issued by a college under the laws of the same State.

A diploma issued under the laws of another State is not necessarily of legal value; but a change in the present Registry Law would seem to be all that is required to prevent incompetent applicants from other States from being admitted to registration in Pennsylvania.

#### MEDICAL NOTES.

**RESIGNATION OF SURGEON-GENERAL HAMILTON.**—Dr. John B. Hamilton, Surgeon-general of the Marine-Hospital Service, has resigned that office and accepted the position of Professor of the Principles of Surgery and Surgical Pathology in Rush Medical College, Chicago. He will be succeeded as Surgeon-general by Surgeon Walter Wyman of the Marine-Hospital Service, who has been his chief assistant in Washington for some time.

**CHANGES IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.**—At a meeting of the Directors of the New York Post-Graduate Medical School and Hospital, H. J. Boldt, M.D., was made Professor of Diseases of Women, William James Morton, M.D., Professor of Electro-Therapeutics, and Aug. Caille, M.D., Professor of Diseases of Children.

**A PROHIBITION MEDICAL CONGRESS.**—A circular has been issued by the managers of the National Prohibition Pack, of Staten Island, inviting representative medical men from all localities in the United States and Canada, to meet in conference on the 15th and 16th of July in the great Auditorium Building of the Park. The chief object of the meeting is to be the comparison of views on the relationship of physiology and alcohol. Many questions are to be discussed relating to alcohol. It is announced that all views will be given an impartial hearing, and that no restraint will be placed on discussion except a time limit. It is

thought that the discussion of these questions by physicians will be a great assistance to the cause of national temperance. Dr. N. S. Davis, of Chicago, will preside.

**THE MEDICAL NEWS.**—Dr. H. A. Hare has retired from the editorship of the Philadelphia *Medical News*, which will be taken by Dr. George M. Gould.

**LAPAROTOMY FOR THE CONTROL OF THE AORTA DURING AMPUTATION.**—In the May number of the *University Medical Magazine*, Dr. Neal Hardy, of Ohio, gives an account of a case in which he successfully performed amputation at the hip-joint for a recurrent lympho-sarcoma, recourse being had to abdominal section in order to give an opportunity for the absolute control of hæmorrhage by immediate compression of the aorta.

**THE UNIVERSITY QUESTION IN ITALY.**—The university question is exercising the minds of educational reformers in Italy. The belief seems to be pretty generally entertained that at present there are too many universities, and a number of different schemes for the reorganization of the whole system of higher education are under consideration.

**MATRIMONIAL PROSPECTS OF THE TRAINED NURSE.**—According to the *Medical Press* an enterprising lady has been making investigation upon the question of matrimony in regard to her sex. She finds that the highest marriage-rate is among trained nurses, and impartial observation would rather tend to support the statement that this is the best field for matrimony which the fair sex enjoys. Whether this is equally true in America is open to doubt. According to the recent reports of the training-schools connected with the Boston City and Massachusetts General Hospitals, only fifteen per cent. of the graduates have since become married.

**MORTALITY OF THE STATE OF NEW YORK DUE TO INFLUENZA.**—The mortality of the State for April was 13,981, or 463 deaths daily, the largest that has ever been recorded for one month; it exceeds that of January, 1890 (the highest previously recorded), by 65 deaths daily; that of April, 1890, by 166, and that of March, 1891, by 118 deaths daily. The increase is due to the epidemic of *influenza*, which beginning in mild form in February, caused an estimated mortality of 1,000 in March, and in April has apparently been the cause of 4,500 to 5,000 deaths, in excess of April, 1890, all allowances being made. This is greater by nearly 1,000 than the estimated mortality from this cause in January, 1890. The onset of the epidemic has been much less rapid than in 1890, when it reached its height in less than one month from its commencement. Outside of the large cities only about 500 deaths have been attributed to this cause. The increase has shown itself in deaths from *acute respiratory diseases*, which caused one-fourth of the mortality, *consumption* (to a much less degree than in 1890), diseases of the *nerve system* (causing one-tenth of all

deaths), and other local diseases in a smaller ratio. The mortality among the aged has been very great, and from diathetic diseases not classified. Returns being received from 5,600,000 population, the annual death-rate for the month is 30.00 per 1,000.

**INSANE IN THE UNITED STATES.**—Bulletin No. 62, issued May 9, 1891, by the Superintendent of the United States Census, contains the following statement: "The total number of insane persons treated in both public and private institutions during the year 1889 was 97,535, while during the year 1881 there were 56,205 treated, showing an increase in the nine years of 41,330, or 73.53 per cent. This percentage of increase, when compared with the percentage of increase of population in the last decade, namely, 24.86, does not indicate an increase in the proportion of insane persons to population, but rather a great increase in the amount of asylum accommodation provided and a willingness on the part of the public to make full use of all the facilities thus provided. The figures for the actual number of insane in the United States can not be determined until the work of eliminating all duplicate reports of cases has been completed. In 1889 there were thirty-eight private institutions in the United States for the treatment of insane, 25 located in the North Atlantic States, 12 in the North Central States, and 1 in the South Atlantic States. The ratio to each 1,000 inhabitants of the whole United States of the insane in public institutions is 1.46, and including both public and private institutions, 1.56."

#### BOSTON AND NEW ENGLAND.

**RESIGNATION OF PROF. H. W. WILLIAMS.**—Dr. Henry W. Williams has resigned the professorship of Ophthalmology in the Harvard Medical School, which he has held since 1871.

**THE MEDICAL REGISTER FOR NEW ENGLAND** is now in the hands of the printer, and will be published as soon as possible.

**YALE MEDICAL SCHOOL.**—The annual address in medicine at the Yale Medical School will be delivered this year by Dr. John S. Billings. The address will be delivered on the Tuesday before Commencement.

**CONNECTICUT MEDICAL SOCIETY.**—The ninety-ninth annual meeting was held in Hartford on May 27th and 28th. Action was taken towards the celebration of the one-hundredth anniversary, which occurs next year. The following officers were elected: President, C. A. Lindsley of New Haven; Vice-President, Cyrus B. Newton, of Stafford Springs; Treasurer, W. W. Knight, of Hartford; Secretary, N. E. Wordin, of Bridgeport.

#### NEW YORK.

**STATE CARE OF THE INSANE.**—The Board having in charge the establishment of State hospital districts under the State Care of Insane Act met recently in Albany and considered the plans and estimates for the proposed detached buildings to be erected on the grounds of the State hospitals for the further accom-

modation of the county insane. The cost of the various buildings is not to exceed \$550 per capita, and they are to be paid for out of the appropriation of \$454,000 made by the legislature at its last session.

**THE BROOKLYN HOME FOR HABITUÉS**, a new institution for the treatment of those addicted to opium, cocaine, chloral and other drugs, has been established in temporary quarters at the Adams homestead on Brooklyn Avenue; though it is in contemplation to erect a commodious building for the Home at a cost of about \$100,000. Among its directors are Drs. T. Gaillard Thomas, Edward G. Janeway, Allan McLane Hamilton, and George F. Shrady, of New York, and Alexander J. C. Skene, Lewis S. Pilcher, Arthur Mathewson, and John C. Shaw, of Brooklyn. Free treatment, it is hoped, can be given to patients recommended by reputable physicians to the extent of one-quarter of the institution, and in order to carry out this provision an endowment fund of \$60,000 is called for, the income of which can be devoted to the maintenance and treatment of the free patients.

### Miscellany.

#### NEW SCHOLARSHIPS AT THE HARVARD MEDICAL SCHOOL.

At a meeting of the President and Fellows of Harvard College in Boston, April 27, 1891, the following letter was read to the Board:

BOSTON, April 20, 1891.

*To the President and Fellows of Harvard College.*

GENTLEMEN:—I enclose a check for \$15,000, and respectfully ask for the establishment of three fellowships of \$5,000 each in the Harvard Medical School, in memory of three physicians who were distinguished for their professional services in this community, namely:

George Cheyne Shattuck, who received an honorary degree from Harvard College in 1807.

John Ware, of the class of 1813, and who received a degree of M.D. in 1816.

Charles Eliot Ware, of the class of 1834, and who received a degree of M.D. in 1837.

All the income that may be derived from these three fellowships may be paid to any one student or member of the medical profession who shall be selected by the Faculty of the Medical School to make such original investigations in medical science as, in their opinion, will be most useful to the profession and the community.

Your obedient servant,

(Signed)

WM. S. BULLARD.

#### THE INFLUENCE OF GASTRIC JUICE ON MICRO-ORGANISMS.

KIANOVSKY<sup>1</sup> has published an extensive work on this subject, in which he comes to the following conclusions:

The healthy stomach, when empty, always contains a large number of different microbes. The number found in the contents of the stomach an hour after a meal, is in direct proportion to the number contained in the food when it was eaten. Gastric juice possesses

<sup>1</sup> Vrateh, 1890.

germinal properties, principally on account of the free hydrochloric acid which it contains. Gastric juice of normal acidity and with a certain amount of free hydrochloric acid, kills a number of the micro-organisms in ingested food, the number killed being in direct proportion to the length of time that the food is in the stomach. In persons with diminished acidity of the gastric juice the number of microbes increases, and these persons are more liable to systemic infection from the alimentary tract.

The author was unable to find any evidence that the presence of micro-organisms was in any way an aid to digestion.

#### IODIDE OF POTASSIUM FOR THE DIAGNOSIS OF PHTHISIS.

STICKER<sup>1</sup> renews an observation made by him a few years ago, which he has in the meantime confirmed, and successfully used for the diagnosis of doubtful phthisis. He finds that where a lesion exists at the apex of a lung, suspected by an impairment of resonance, and alteration in pitch or a harsh respiratory murmur, but without râles or blowing murmur, the latter may be produced by giving, for a few days, small doses of iodide of potassium. It seemed as if the drug stimulated secretion, especially in the neighborhood of diseased tissue, thus giving rise to râles. If moderate doses of the iodide be administered to a healthy person, no changes can be detected in the lungs; but in a case of diffuse dry bronchitis, in the course of a few days an extensive moist catarrh, with fine and coarse moist râles, results. Similar manifestations appear in the area of circumscribed pleural adhesions or pleuritic roughenings. Not rarely the evidences of local reaction are gradually obscured by the signs of diffuse catarrh. In four cases of suspected tuberculosis, in which repeated physical examination of the lungs proved negative, the administration of the iodide for diagnostic purposes produced distinct signs of localized reaction in one or both apices, with tuberculous sputa.

#### THE NUTRITIVE VALUE OF RECTAL INJECTIONS OF EGG ALBUMEN.<sup>2</sup>

THE assertions of Voit and Bauer and Eichhorst to the effect that egg albumen is absorbed by the rectum only in the presence of a certain proportion of chloride of sodium, but is returned unaltered with the feces if this reagent be absent, has led Huber to investigate this point anew, and to make his observations on man, and not on dogs, as his predecessors had done. The experiments were planned with great care, and the quantity of albumen removed from the body, both by the urine and the feces, was estimated. As the outcome of several series of experiments, the results of which show a great agreement, the author gives as his conclusion that egg albumen simply beaten up is absorbed by the rectum, but only in very small quantities, and consequently a nutrient enema of this kind possesses hardly any value. When, however, a certain amount of common salt is added (15 grains to each egg in the present series of experiments), the quantity of albumen absorbed is doubled. Peptonized egg albumen was absorbed in very slightly greater proportion

than that treated with common salt, but of peptonized albumen with salt, between sixty and seventy per cent. was absorbed, and we, therefore, have in this mixture an extremely valuable material for nutrient enemata.

In no case of Huber's were the enemata expelled; nor was albuminuria ever found to occur after their use.

#### THE HEALTH OF THE AMERICAN GIRL.

DR. G. J. ENGELMAN<sup>1</sup> renews the attack against the social condition of the day, which by forcing an over-load of mental and physical work upon girls at and about the time of puberty (that is roughly speaking between the ages of twelve and sixteen or eighteen), imperils their future health. At a time when a large number of girls need the best possible conditions in order to develop into strong and healthy women, an additional burden is put upon them,—among the well-to-do classes excessive mental work, and school competition, sometimes also severe social duties; among the needy classes, long hours of fatiguing physical work. A breaking-down at this time may mean more or less invalidism for years, or even for life, lack of development and lessened capacity for reproduction. The symptoms pointing to over-work are many: irregularity or stoppage of menstruation, nervousness, loss of appetite and of growth, anemia, and various other well-known conditions. Especially is harm done by the lack of proper precautions during the menstrual period. The importance of rest at that time is not understood by the girl and often neglected by her mother.

The author quotes several cases illustrating the way that harm is done, and the results; and, in summarizing, says that harm is done, in education, by over-brain work and nerve-strain, with neglect of the physical system; in labor, by nerve-strain and partial or incomplete muscular activity; in both, by influences which are inseparably connected with, and complicated by, causes more active and independently potent. These causes are: The ignoring and neglecting of functional hygiene; physical and emotional strain of society; improprieties of dress; and over-stimulation of the senses. The remedy is: attention to woman's peculiar organization and the cyclical waves of her dominant function; diminished brain work and nerve stimulation, with increased and coördinate physical exercise; increased protection and diminished compression of dress; self-knowledge and individual care during menstruation. The nerve and emotion strain of class competition must be abolished; the stress of constant work, the train of thought and the routine of regulation must be broken; the nerve-strain varied by healthful pleasures and physical exercise in the open air; all relieved more or less, according to individual necessities, during periods of heightened susceptibility.

Whilst the initial causes of ill-health in the school-girl may readily be overcome, the dangers which beset the laboring girl, though equally evident, are more difficult of removal. The years of development should be respected, and the continuity of labor broken; rest and change afforded frequently for short periods.

The author closes with a plea for the self-care of the girl and her proper physiological instruction by

<sup>1</sup> Centralblatt für klin. Med.

<sup>2</sup> Medical Chronicle, April, 1891.

<sup>1</sup> Annals of Gynecology and Pædiatry, April, 1891.

the mother, who should understand that the perfect development of the female function, with the maintenance of this function, once developed in a healthy condition, is essential to the perfect development of the girl and the perfect health of the woman.

# OBITUARY. FORDYCE BARKER, M.D.

Dr. FORDYCE BARKER died in New York, on Saturday afternoon, May 30th, at the age of seventy-three.

Dr. Barker was born at Wilton, Me., and graduated from Bowdoin College in the class of 1837. He studied medicine for a short time in Boston under Dr. H. I. Bowditch, then in Edinburgh and Paris, receiving a degree of M.D. at the latter city in 1844. He began the practice of medicine in Norwich, Conn. In 1845 he was made Professor of Obstetrics at the Bowdoin Medical College. In 1850 he went to New York, having been appointed to the chair of midwifery in the New York Medical College. He subsequently became Professor of Clinical Midwifery and the Diseases of Women in the Bellevue Hospital Medical College, a position which he held for many years, and on retiring was made Professor Emeritus.

For many years Dr. Barker has been one of the most prominent of the medical men of New York, and in fact of the United States. He was the attending physician of General Grant during his last illness, and one of those summoned to President Garfield. He was the first president of the American Gynecological Society, in 1876 and 1877. From 1879 to 1884 he was president of the New York Academy of Medicine, and inaugurated the great development of the Academy, and especially of its library. He was consulting physician to Bellevue Hospital, St. Elizabeth's Hospital, the Nursery and Child's Hospital, the Cancer Hospital and surgeon to the Woman's Hospital. He was an honorary member of several societies in this country, and also of the obstetrical societies of Edinburgh and London. He received the honorary degree of LL.D. at the three-hundredth anniversary of the Edinburgh University. He contributed much to medical literature.

Dr. Barker possessed an exceptional professional acumen and a keen perception in medical matters. He was a leader in debate, a very popular lecturer, and was listened to with interest, in spite of a physical disability in speech, from which he suffered for many years. He was a man of great energy, which he contributed to everything tending towards the promotion of the interests of the profession. His circle of acquaintance among medical men was probably larger than that of any other American physician. He knew personally most men famous in the profession, and many out of it, both in America and also in Europe, having passed every summer on the latter continent for more than thirty years. He may be said to have been the Sir Henry Holland of America. He was an intimate friend of Trousseau and Du Bois and other well-known members of the Paris University when it was at its height. He was always genial, and of unbounded hospitality. He possessed the gift of imparting to others the spirit of hospitality, a striking example of which appeared in the complimentary dinner given to Dr. O. W. Holmes by the profession of New York in 1883 at his invitation and over which he presided. He has been a frequent visitor to Boston, his last appearance here being at the annual meeting of the Massachusetts Medical Society in 1889.

Dr. Barker has been in failing health since 1885, but has since that time appeared in public, the last time being at the opening of the new building of the New York Academy of Medicine. He had not retired from practice, but saw patients to within a few days of his death. He had suffered for some time from interstitial nephritis and valvular disease of the heart, but the immediate cause of his death was cerebral hemorrhage, which occurred two days before he died.

## PRESCRIPTIONS.

NAPHTHALIN is recommended by Minerbi and by Calphe for dysentery:

R Naphthalin . . . . . gr. xv.  
Olei theobromae . . . . . q. s. M.

For one suppository, or

R Naphthalin . . . . . ʒ i.  
Olei olive . . . . . ʒ iv. M.

For a rectal injection, several times a day. The latter is useful also for oxyuris vermicularis in an adult. For children with pin worms the following injection is used:

R Naphthalin . . . . . gr. xv.  
Olei olive . . . . . ʒ x. M.

SCURVY.—Tschelzow<sup>1</sup> considers an absolute milk diet a specific for scorbutus. He begins with about four glasses of milk a day, and increases it at the rate of a glass every day or two.

DIABETES MELLITUS.—Valentini<sup>2</sup> has found creosote of value in the treatment of this disease. In two cases reported, four drops were given daily, and gradually increased to ten drops. The sugar disappeared and did not return even after the patients again used starchy food.

CHOLAGOGUE.—Huclard<sup>3</sup> uses the following:

R Sodii benzoatis }  
Acidi salicylici } . . . . . aa ʒ j.  
Pulv. rhei }  
Pulv. nucis vomici . . . . . gr. vj. M.

Divide in capsules No. XVI. One after each meal.

ACETANILID AND CAMPHOR.—Chesmiutzeff<sup>4</sup> recommends that camphor be given with acetanilid in order to overcome the depressing effects of the latter. He has had good results with this combination in the treatment of pneumonia.

R Acetanilid . . . . . gr. iij.  
Camphor . . . . . gr. jss. M.

For one capsule. This may be repeated in four hours.

<sup>1</sup> Med. Rev. f. Baln., No. 7, 1890.

<sup>2</sup> Nouveaux Remedes, March 8th.

<sup>3</sup> Médecine Moderne.

<sup>4</sup> Deutsche med. Woch., May 14th.

## METEOROLOGICAL RECORD,

For the week ending May 23, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Deaths reported 3,121; under five years of age 1,127; principal infectious diseases (small-pox, measles, diphtheria and croup, acute lung diseases 491, consumption 387, typhoid fever 119, diarrhoeal diseases 106, diphtheria and croup 101, measles 52, scarlet fever 50, cerebro-spinal meningitis 24, whooping-cough 24, erysipelas 10.

From measles New York 15, Brooklyn 13, Chicago 9, New Orleans 5, Philadelphia 2, Boston, Nashville, Charleston and Portland 1 each. From scarlet fever New York 20, Brooklyn 13, Philadelphia 8, Chicago 7, Boston and Haverhill 1 each. From cerebro-spinal meningitis Chicago 9, New York 7, Philadelphia, Brooklyn and Lowell 2 each, Worcester and Cambridge 1 each. From whooping-cough New York 10, Chicago 5, Philadelphia 3, Washington 2, Brooklyn, Boston, Nashville and Lawrence 1 each. From erysipelas New York and Washington 2 each, Chicago, Philadelphia, Brooklyn, Boston, Nashville and Lynn 1 each.

## OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MAY 23, 1891, TO MAY 29, 1891.

Direction of the Secretary of War, leave of absence for three months, on surgeon's certificate of disability, is granted Captain M. V. LORIMER, U. S. ARMY, assistant surgeon. S. O. 119, Par. 4, A. G. O., Washington, May 25, 1891.

Leave of absence for one month, with permission to apply for an extension of one month, is granted Captain P. L. BROWN, assistant surgeon, U. S. ARMY, S. O. 59, Par. 4, Department of the Missouri, St. Louis, May 26, 1891.

## OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE HOSPITAL SERVICE, FOR THE TWO WEEKS ENDING MAY 25, 1891.

ANASKE, JOHN, surgeon. Granted leave of absence for seven days. May 22, 1891.

BROWN, FARRAN, surgeon. Granted leave of absence for twenty-one days. May 11, 1891.

GUTHRIE, G. M., assistant surgeon. Relieved from special

duty at New York, N. Y., ordered to San Francisco, Cal. May 11, 1891.

GREENVELT, J. F., assistant surgeon. Relieved from duty at New York Marine Hospital, ordered to Gulf Quarantine, May 22, 1891.

YOUNG, G. B., assistant surgeon. Granted leave of absence for thirty days. May 11, 1891.

### PROMOTIONS.

PERRY, T. B., passed assistant surgeon. Commissioned as such by the President. May 23, 1891.

WOODWARD, R. M., passed assistant surgeon. Commissioned as such by the President. May 23, 1891.

### DEATHS.

GEORGE D. BRUCE, M.D., of Pittsburgh, Pa., died, May 29th, aged seventy-nine.

DAVID PHILLIPS, M.D., died suddenly in New York, May 28th, aged thirty-nine. He had been Professor of Chemistry in the College of Physicians and Surgeons, and was on the medical staff of the Presbyterian Hospital, and of the Manhattan Eye and Ear Infirmary.

JAMES W. WHITE, M.D., D.D.S., died suddenly in Philadelphia, May 27th, aged sixty-seven. He was President of the S. S. White Dental Manufacturing Co., President of the Maternity Hospital, and President of the Philadelphia City Department of Charities and Correction.

JOSEPH H. STREETER, M.D., M.M.S.S., died in Roxbury, May 30th, aged seventy-one. He had been in active practice in Roxbury for more than forty-five years, where he had served as City Physician, in the Legislature, on the School Committee, and in other positions of trust.

GEORGE ELIOT, M.D., M.M.S.S., died in Venice, May 22d, aged twenty-five. He was Surgical House-Officer in the Massachusetts General Hospital in 1889-90, his term expiring in August. After leaving the hospital, he went abroad for study. While travelling in Italy he was attacked with typhoid fever, from which he died.

### BOOKS AND PAMPHLETS RECEIVED.

The Fifty-eighth Annual Report of the Boston Lying-in Hospital. 1890.

Sixth Annual Report of the Board of Health of the City of Newport, R. I., for the Year 1890.

The Sixty-seventh Annual Report of the Officers of the Retreat for the Insane, at Hartford, Conn., April, 1891.

Transactions of the Twelfth Annual Meeting of the American Laryngological Association held in Baltimore in May, 1890.

Collected Contributions on Digestion and Diet. By William Roberts, M.D., F.R.S. Philadelphia: Lea Brothers & Co. 1891.

The Inter-Cranial Circulation, and its Relation to the Physiology of the Brain. By James Crippie, M.D. Edinburgh: James Thine. 1890.

The Surgical Treatment of Wounds and Obstruction of the Intestines. By Edward Martin, M.D., and H. A. Hare, M.D. Philadelphia: W. B. Saunders. 1891.

Corrosive Sublimate as a Disinfectant against the Staphylococcus Pyogenes Aureus. By C. A. Abbott, M.D., Assistant in Bacteriology and Hygiene, Johns Hopkins Hospital. Reprint. 1891.

Annual Reports of the Winnipeg General Hospital for 1889 and 1890; The Manitoba Medical College, Winnipeg, 1890-91; and a By-Law to Provide for the Public Health of the City of Winnipeg, 1885.

L'Affaire des Magnétiseurs de Braine-le-Chateau. Examen Critique du Rapport des Médecins Experts. Par J. Delbault, Professeur à l'Université de Liège. Liège: Imprimerie Emile Pierre & Frère. 1891.

An Address Delivered at the Opening of the Twenty-first Annual Meeting of the Medical Society of the State of California, April, 1891. By W. R. Cluness, M.D., President, Sacramento, Cal. Reprint. 1891.

The Effect of Arterio-Sclerosis upon the Central Nervous System, by George J. Preston, M.D., Baltimore; and Report on the Ophthalmoscopic Examination of Dr. Preston's Cases, by Harry Friedenwald, M.D., Baltimore. Reprint. 1891.

A Text-Book of Practical Therapeutics, with Especial Reference to the Application of Remedial Measures to Diseases and their Employment upon a Rational Basis. By Holman Amory Hare, M.D. Second edition, enlarged and revised. Philadelphia: Lea Brothers & Co. 1891.

Five Cases of Suprapubic Cystotomy: Three for Stone, One for Tumor in the Bladder, and One for Exploration with Catheterization of the Ureters: One Death. By W. W. Keen, M.D., Professor of the Principles of Surgery, Jefferson Medical College, Philadelphia. Reprint. 1891.

## Address.

JAMES THACHER, M.D., OF PLYMOUTH, MASS.<sup>1</sup>

BY JAMES B. BREWSTER, M.D., OF PLYMOUTH, MASS.

MR. PRESIDENT AND FELLOWS OF THE MASSACHUSETTS MEDICAL SOCIETY:—From the settlement of the colonies until the end of the first quarter of the eighteenth century, medicine in this country can hardly be said to have existed as a distinct profession.<sup>2</sup> Almost the only medical practitioners were the clergy, many of whom combined with their pastoral duties the healing of the sick. They ministered to both body and soul in a manner alike heroic. Among the medical authors of that time appears the name of Rev. Thomas Thacher, the author of the first medical publication in America, issued in 1677, entitled, "A Brief Rule to Guide the Common People of New England how to order themselves and theirs in the Small Pocks and Measles";<sup>3</sup> also of Cotton Mather, Jared Eliot, and other clergymen, contributors to the scanty literature of medicine. Scattered throughout the colonies there were a few regularly educated physicians, but their number was small, and their influence limited. At first they were graduates of the different European schools; later, some of the graduates of American colleges sought in Europe opportunities for professional instruction not attainable in America.<sup>4</sup> Two of the early presidents of Harvard College, Charles Chauncy and Leonard Hoar, were graduated in medicine at Cambridge, England.<sup>5</sup> John Clark, an English physician, practised in Boston from 1638 to 1664.<sup>6</sup> William Douglas, M.D., a Scotchman, educated at Leyden and Paris, who is remembered as Boylston's unscrupulous opponent in the practice of inoculation, was a practitioner in Boston, of great repute, from 1716 to 1750. Dr. Thomas Boylston, the father of the introducer of inoculation, was a graduate of the University of Oxford, and settled in Brookline in 1635. Later, we recall the names of Isaac Rand, William Aspinwall, John Cutter, Thomas Bulfinch, Benjamin Gale, John and Joseph Warren, and others who might be mentioned, as eminent and skilful physicians of the time. Yet, notwithstanding these most illustrious exceptions, we must remember that the great mass of practitioners of medicine previous to the Revolution were ignorant pretenders, without a medical degree, or any warranty save that they had served an apprenticeship with some local dispenser of herbs and the more disgusting remedies then in vogue.

It is difficult to appreciate how low the standard of medicine then was; Dr. Beck says in his "Historical Sketch,"<sup>7</sup> that "in point of respectability, medicine undoubtedly stood lower than either the legal or theological professions. The religious difficulties in England had filled the ranks of the latter with men of learning, talent and piety, while the offices of honor and emolument under the Crown offered allurements sufficiently powerful to induce many who were distinguished in law to emigrate to the western world. With medicine it was far otherwise; accordingly, for a long time, with

some few exceptions, only those who had failed to attain respectability or employment at home, would venture on so precarious an experiment. Nor were the young native physicians, for a long time, calculated to remedy the evil. There were neither lectures, schools, nor hospitals, which could be resorted to, and the expense of a foreign education was an insurmountable obstacle."

Even so late as 1753, we are told by the *Independent Reflector*, a paper published in New York, that that city with ten thousand inhabitants could boast of more than forty gentlemen of the faculty, the greater part of whom were mere pretenders to a profession of which they were entirely ignorant, and convincing proofs of their incapacity were exemplified in their iniquitous practices. The advertisements they published proved them ignorant of the very names of their drugs.<sup>8</sup>

It is estimated by Dr. Toner, in the "Annals of Medical Progress," that at the time of the Revolution the colonies contained about three millions of inhabitants, and from three thousand to thirty-five hundred physicians, of which number not more than four hundred had received a medical degree. The first course of anatomical lectures with demonstrations delivered in New England was given by Dr. John Warren, then surgeon of a military hospital in Boston, during the year 1780.<sup>9</sup>

Previous to the middle of the eighteenth century, obstetrics was not considered as belonging to the medical profession; all births were attended by females. Dr. James Lloyd, returning from Europe in the year 1753, where he had been a pupil of the celebrated Smellie, first introduced the custom of attendance by male practitioners,<sup>10</sup> which afterwards became general.

Thus, without attempting to follow more fully the history of medicine in this country during the eighteenth century, we see that the only opportunity for a young man of moderate means to enter the medical profession was by associating himself with a local practitioner. This association was generally by apprenticeship for a term of years, usually five or six. The apprentice was taken at an age much younger than we should now think a lad ready to commence the study of a profession. Dr. John Bard,<sup>11</sup> when fourteen years of age, was apprenticed to Mr. Kearsley, an English surgeon at Philadelphia, who treated him with great rigor, and subjected him to the most menial employments. Dr. Benjamin Rush was apprenticed at the age of fifteen; Dr. James Lloyd, at seventeen, for a period of five years; also Dr. Daniel Drake, while in his sixteenth year. The apprentice was expected to perform the disagreeable duties about the barn and farm, as well as those more professional—such as the preparation of drugs, medicaments, and plasters—with occasional opportunities to assist at minor operations, and was dependent more upon his own observations than upon instruction received, for acquiring a knowledge of his profession. Of books there were but few, and these chiefly of the older writers,—Hippocrates, Galen, and Sydenham, with possibly some of the more recent works of Van Sweeten, Huxham, Haller, Pott, Smellie, and Hunter; but not often were more than three or four of these found in the possession of any one individual.

<sup>1</sup> Being the Annual Discourse delivered before the Massachusetts Medical Society, at the One-hundred and Tenth Annual Meeting, June 10, 1891.

<sup>11</sup> Thacher: *Medical Biographies*, p. 96.

With this short prelude as to the status of medicine and the medical profession in the eighteenth century, I ask your attention to the subject of my paper,—JAMES THACHER, M.D., of Plymouth, Massachusetts.

Dr. Thacher was descended from Anthony Thacher, who came to this country from England in the year 1635. He was born at Barnstable, February 14, 1754. His father was John Thacher, his mother was daughter of Samuel Norton, Esq., of Chilmark, Martha's Vineyard, and grand-daughter of Governor Coddington, of Rhode Island. With only such preparation as could be acquired while living upon one of the sandy farms of Cape Cod, he was, at the age of sixteen, apprenticed to Dr. Abner Hersey, of Barnstable. That his preceptor was an eccentric and austere man, with less of the science than the art of medicine, appears from his student's interesting and somewhat amusing account of him. Dr. Hersey's advantages of education were greatly deficient, he having labored with his father in husbandry during early life. He commenced the study of medicine under his brother James, of Barnstable, a physician of reputation and extensive practice. After a pupilage of about one year, his brother's death proffered him at the age of nineteen, the benefit of that brother's name and the field of his professional labors. At a youthful period of life, perhaps unexampled in the annals of medicine, and under the disadvantages of a penurious education, young Hersey began his career, and ever after pursued it with fidelity and zeal. He at once embraced the whole circle of practice which his brother had enjoyed, and it was not long before he acquired the confidence and respect of the people. For many years he commanded without a rival the whole practice upon Cape Cod—a distance of more than forty miles, containing a population of seven or eight thousand—controlling at pleasure his practice and his fees. As a surgeon he was considered judicious and skilful, though he never performed a capital operation.

Dr. Hersey was subject to an hypochondriacal affection, and in his domestic character was eccentric in the extreme,—a compound of caprice and whims. Domestic happiness and social intercourse were strangers in his family. He oftener chastened by his frown, than cheered by an expression of approbation. He adopted a very abstemious mode of living, rejecting animal food, ardent spirits and wine, confining himself chiefly to a diet of vegetables and milk. But in nothing was his singularity more conspicuous than in his manner of dress. His garments were of a fashion peculiar to himself, remarkably large and loose, and lined throughout with baize. Such was his whimsical fancy, that he had a great-coat made of tanned leather. Seven calf skins were cut and formed into an outer garment as a defence against the rain. He was by nature choleric in his temper, and abrupt in his manners; and when in his peevish moods, it was common for him to express himself in such language as this: "I had rather be chained to a galley oar, than suffer such vexation."

A curious instance of this kind occurred when the widow of his brother contemplated making him a visit. She informed him by letter of her intentions. The doctor, knowing that she would appear in a style rather different from that to which he had been accustomed, was greatly agitated, and immediately answered the letter as follows: "Madam, I cannot have you. I have neither hay nor corn for your horses, I have

no servants in my family, and I had rather be chained to a galley oar than wait upon you myself."

He died in the sixty-sixth year of his age, leaving no children. By his will he bequeathed to Harvard College five hundred pounds, as an additional endowment of the professorship to which his brother, Ezekiel Hersey, of Hingham, had previously given a larger sum.

Dr. Thacher completed his five years' apprenticeship in the twenty-first year of his age, at a most eventful period in the history of our country. The battle of Bunker Hill had just been fought. All New England had become the theatre of civil war, and every member of the community was stirred with the deepest anxiety and patriotic enthusiasm. Our young doctor says of himself: "Participating in the glorious spirit of the times, and contemplating improvement in my professional pursuits, motives of patriotism and private interest prompted me to hazard my future in the conflict for independence."<sup>12</sup>

In taking this step, he met with no encouragement, either from his own family or from his late preceptor. All urged in opposition his youth, and the manifest hopelessness of the cause. However, his youthful ardor found in Joseph Otis, Esq., more sympathetic counsel. That gentleman not only commended his purpose, but furnished him with a letter of introduction to his (Otis's) brother-in-law, James Warren, Esq., President of the Provincial Congress. Through James Warren's influence his name was added to the list of candidates for examination; and he awaited the appointed day with anxiety and suspense, lest his stock of medical knowledge should be deemed inadequate, and his hope be blasted. That the examination was reasonably close and severe, covering the topics of anatomy, physiology, surgery and medicine, is apparent, since, of the sixteen examined, six were privately rejected as unqualified.<sup>13</sup> Having successfully passed this test, he was appointed surgeon's mate in the provincial hospital at Cambridge, Dr. John Warren being the senior surgeon. July 15, 1775, he assumed his duties. Dr. Josiah Bartlett was associated with him in a similar capacity. This hospital consisted of several private but commodious houses appropriated for the purpose, and contained a number of soldiers wounded at Breed's Hill, as well as many sick of various diseases.

The following February upon the appointment of Dr. John Morgan as Director-General of Hospitals, our young surgeon was subjected to another examination by that gentleman, and appointed mate to Surgeon David Townsend, and assigned to Colonel Asa Whitcomb's regiment, stationed upon Prospect Hill. This regiment was one of the few which were permitted to enter the town of Boston, after it was evacuated by the British. At this time, small-pox prevailing, he was inoculated by his friend, Dr. John Homans, and passed successfully through the disease, not being ill in bed a single day. He accompanied his regiment upon the expedition to Ticonderoga, and participated in that disastrous retreat, which afterwards proved to have been one of the factors in bringing about the ruin of Burgoyne's army by drawing that general into the interior. The term of service of Whitcomb's regiment having expired, Dr. Thacher was appointed to the general hospital. While in this hospital at Albany, he enjoyed fine opportunities for

<sup>12</sup> Thacher: *Military Journal*, p. 25.

<sup>13</sup> *Loc. cit.*, p. 34.

professional improvement, large numbers of officers and soldiers of both armies being assembled there; among these was General Benedict Arnold, suffering from a fracture of the leg, whom the doctor found an exacting and unreasonable patient.

The following November, 1778, Dr. Thacher was appointed surgeon of the First Virginia Regiment, with which he remained until the next June, when, upon the invitation of Dr. Townsend, he exchanged into the First Massachusetts, commanded by Colonel Henry Jackson. His relations with the Virginia officers had been most pleasant, but he believed it to be more advantageous to serve in a regiment with officers from his native State. While with Colonel Jackson's regiment he participated in various minor engagements and skirmishes, and was present at the execution of Major John André.<sup>14</sup> Of that melancholy sacrifice of a brave and chivalrous young officer to the stern and relentless rules of war, he has given us in his "Military Journal" one of the best accounts extant.

In July, 1781, Colonel Alexander Scammel, formerly adjutant-general of the army, formed a select corps of light infantry, chosen from the most active and efficient of the New England soldiers. The honor of an appointment as surgeon to the troop was offered to Dr. Thacher, and accepted by him. This troop was intended for active and hazardous duty in advance of the main army. They were present at the siege of Yorktown, which terminated in the surrender of Lord Cornwallis. This incident of the war afforded Dr. Thacher the greatest satisfaction. He speaks of it as among the blessed privileges and richest incidents of his life, that he assisted at the siege and capture of a British army.

January 1, 1783, in accordance with a resolution of Congress reducing the army in view of the near approach of peace, Dr. Thacher resigned his commission, and left the military service with honorable testimonials as to the faithful discharge of the various duties which had devolved upon him. We have followed thus minutely his military career, as it was the school which liberally educated him. He entered the army an obscure lad of twenty-one years, poorly equipped with professional knowledge, and entirely deficient in worldly wisdom; he emerged after seven and a half years spent in the enjoyment of unusual facilities for advancement in his profession, an accomplished physician and surgeon. He had acquired also those social qualities which were not less important to his future success, by association as guest and friend with the most distinguished and cultured officers of the Revolutionary army.

He retired from the army July 1, 1783, and in the following March established himself at Plymouth, Mass., as a practitioner of medicine and surgery. The prestige which he brought with him speedily obtained for him a large and lucrative practice. His fame soon spread, and he was frequently called to the neighboring towns for consultation, especially in cases of surgery. While pursuing an arduous and extensive practice, he was also engaged in teaching. Usually, as members of his family were six or eight students whom he instructed by recitations and demonstrations. It has been related to me by an old lady<sup>15</sup> who remembered the doctor very well, that quite a serious local sensation was created by the suspicion that some of

the dissecting material for his demonstrations was obtained from a neighboring churchyard. A curiously deformed individual was believed to have been resurrected by the students, and a mob collecting threatened the doctor's house, and interrupted for a time his course of instruction.

### PULMONARY SYPHILIS IN THE ADULT.<sup>1</sup>

BY THOMAS E. SATTERTHWAITE, M.D., NEW YORK CITY.

My excuse for bringing this vexed question before the profession at this time is that I have some personal experience to present that will, I think, contribute something towards its solution.

And I may say at the outset, that the importance of syphilitic lung affections has been very much underestimated by physicians; and I do not much blame them, because the subject has always occupied an obscure corner in our text-books, or has been altogether omitted.

These statements of mine lead us to the inference that there is both a negative and an affirmative position, and I could prove it satisfactorily to-day by an appeal to you who are here. For some of you would tell me plainly that you do not believe in the existence of pulmonary syphilis: others of you would state positively that you have both seen it and treated it successfully. Perhaps some of the former may be among my syphilographic friends, who, like Baemler, have written much on the disease in some of its special types; and yet with him they may feel compelled to state that they are not sure of ever having seen a genuine case.<sup>2</sup> Indeed, I am willing to concede that such a position is within the range of possibility, though not of probability. At any rate the majority of general practitioners throughout this country to-day would, I am quite confident, affirm that they have never seen lung syphilis.

In my clinics at the Post-graduate Medical School, during my experience of eight years, I was repeatedly told by medical men that syphilis did not occur *at all* in their practice, being quite unknown to them. And yet syphilis is really a comparatively common disease; and when any one has once learned to recognize it under its protean forms, he feels astonished at having failed in making the diagnosis. And I am quite willing to join with such a one and cry, *Peccavi*.

But both in our own country and in all civilized lands there are to be found numbers of prominent practitioners who are ready to affirm the existence of pulmonary syphilis, and as the result of their deliberate opinion derived from personal knowledge; and yet I will willingly admit that there have been good grounds for holding conservative views, especially among those whose practice has not brought them into contact with pulmonary diseases. These grounds are briefly as follows:

In the first place, some syphilologists have said nothing on the subject, denied its existence, or even have spoken with harsh criticism of those on the affirmative side; and all this, we may presume, in per-

<sup>15</sup> Mrs. Mary W. Russell.

fectly good faith. Thus Jonathan Hutchinson,<sup>2</sup> the veteran dermatologist, in his very recent work published last year, has given us a chapter on pulmonary syphilis, under the guise of quotations from Moxon. So, too, Mauriac<sup>3</sup> in his equally recent treatise, has written a special chapter on the same topic; but, after citing a number of well-known cases from previous authors (*without adding any of his own*), he takes occasion to blame the profession for believing that these cases are true examples of the disease. Fournier,<sup>4</sup> in an earlier work, which exhibits much laborious zeal in compilation, has gone so far as to state: "It is almost useless to say that this secondary dyspnoea (in lung syphilis) is a symptom without lesion, *sine materia*. You will search in vain for an explanation, from any pulmonary change. Percussion and auscultation will reveal nothing but what is absolutely normal in the thoracic organs."

Are these fair examples of the narrow lines within which some of the specialists of to-day do their work? Such specialists would say, "It cannot be thus, because I have not seen it"; as if any specialist is a complete master even in his own field. If they know it all, then there is nothing else to know. But we know better.

And yet the profession is awe-struck, thinking that, if the specialist cannot speak with authority, who can? Herein they make a mistake. For pathology and pathological anatomy are, in most departments of medicine, far in advance of mere clinical knowledge; and they ought to retain an advanced position. The former are rapidly approaching the position of exact sciences; the last named will continue to be always more or less unsatisfactory, so long as its teachings are rendered uncertain by unknown physiological laws, individual peculiarities and personal misinterpretations. At the same time, we should not place our confidence too unreservedly in the pathologist who acquires his information from laboratory researches only; for he often makes gross errors, as we are constantly seeing in our every-day experience. The pathologist may be at fault in his technique or in his interpretation of facts, or in analogical reasoning; and my statements will be sustained by any one who has had a fair experience in laboratory work. Great pathologists have committed many errors; why should not lesser mortals? And yet both pathology and clinical teaching are mutually indispensable to a correct understanding of facts, and as a basis for reasoning; and our greatest advances are only made when the pathologist works in the light of clinical data.

But I am anticipating. Let us go back a little, while we are still studying the negative side of our case.

In 1820, when John Hunter published his "Treatise on the Venereal," he said, speaking of syphilis, "we have not yet had every part of the body affected, the heart, stomach, liver, kidneys nor other viscera, although such cases are described by authors." And even the renowned Ricord, of Paris, in editing Hunter's book many years later,<sup>5</sup> gave cogent reasons for his disbelief that certain pulmonary affections described by Depaul, and characterized as peculiar to syphilis, were in any way related to it as cause and effect. And there has been also a conservative spirit among clinicians.

Bayle was in doubt as to it, Laennec<sup>7</sup> and Audral,<sup>8</sup> both prominent teachers in their day, made no allusion to it. Even quite recently it was omitted from one of our best practices,<sup>9</sup> and Fagge,<sup>10</sup> in his excellent book, criticised severely the affirmative statements of Moxon, Goodhart, Green and Pye-Smith, urging that the alleged relations between phthisis and syphilis might prove to be mere coincidences; notwithstanding which, he found himself forced to admit that during a ten-year service at Guy's Hospital he had seen no less than thirteen cases of general syphilis followed by a fatal lung affection.

The negative side has also derived, at times, strength from pathologists. Thus Virchow, in his early career (1858), found himself at a loss for criteria in distinguishing pulmonary tuberculosis from syphilitic phthisis;<sup>11</sup> and Zeigler, in his recent work,<sup>12</sup> follows in the wake of these early views. He does not deny the existence of the disease, but intimates that its pathological products are not to be positively differentiated at the autopsy. But neither of these men would be willing to affirm that syphilis of the lungs does not exist; rather that there are at present grave difficulties in the way of a positive diagnosis from post-mortem appearances. Now let me grant that such is the case. The difficulties are undoubtedly great; but are they insurmountable? This is the question for us to determine.

I believe that I have now fairly outlined the negative position. Let me be equally fair with the other side. First, it may be said that the greatest of all the early pathologists, Morgagni, described lung syphilis in his epistles,<sup>13</sup> intimating that Valsalva was the real discoverer of the disease about one hundred years earlier (1704). Morgagni also spoke of Luetic Phthisis, in his "De Sedibus,"<sup>14</sup> where he wrote that it is seen "somewhat more frequently than you will easily imagine from the reading of most books." So that for nearly two hundred years we have been adding to our information on the subject, even if most of the data have been exceedingly misleading and unsatisfactory.

It seems now to be generally conceded by concurrent medical opinion that the next decided step in advance was made when Depaul, in 1837, described a peculiar fibroid induration of the lungs in the congenital syphilis of infants, whose visceral lesions are more easily recognized than those of the acquired disease. Then, following out this same line of observation, he found a somewhat similar condition in two adult patients where the lungs, on post-mortem examination, were seen to have "purulent foci, bronchiectases and purulent infiltrations."<sup>15</sup>

From this point on, France did much to solve the question before us; and it is but just to say here, that in particular Lagueau, in his "Thèse de Paris" of the same year (1851), laid down postulates that reflect a lasting credit on his name. It is unfortunate that our praise comes so tardily to his work. From an analysis of fifty-three cases he found that syphilis might act on the lungs and bronchi in several ways: First, by producing affections which are generally slight, consisting of acute inflammation of the bronchi and parenchyma of the lungs; extensive inflammation of the

bronchi; asthma and chronic inflammation of the bronchi. Or, by producing serious affections, described by most authors under the head of phthisis; comprising ulcerous chronic inflammation of the parenchyma of the lungs and the lymphatic ganglia; inflammation of the pleura, and syphilitic tubercles (miliary or gummy deposits). Or, by aggravating and hastening the development of pre-existing disposition to tubercle.

We shall see that in the lapse of over forty years we can fairly criticise the truth of these axioms. In England, Munk<sup>16</sup> followed Depaul, giving a satisfactory review of the subject; but it was reserved for Stokes<sup>17</sup> to furnish us with certain definite clinical signs; for, said he, in describing a case of supposed phthisis: "See whether there be any syphilitic taint, and if so, examine for peritonitis of the chest. Secondary syphilis," he says, simulates phthisis, and exhibits a peculiar bronchial irritation." He observed that with a large amount of pulmonary tissue involved, the clinical signs were comparatively few. Graves,<sup>18</sup> following in 1848, upheld these views, adding that pulmonary syphilis was *not* a modern discovery. He based his diagnosis on the success of anti-syphilitic remedies where the patient had the physical signs of (tubercular) phthisis.

The next contribution appears to have come from Weber in 1852.<sup>19</sup> He described the pathological aspect of the consolidated lung under the term "white hepatization," a phrase that later led to the name "white pneumonia," by which the fibroid lung of syphilis is now known among pathologists. To the practised eye there is something fairly distinctive in this white pneumonia, so that one can almost see at a glance on post-mortem examination that we have a syphilitic lung. It is best seen in the earliest or middle stages of infiltration, contrasting sharply with the deep gray or bluish coloration of fibroid phthisis, or the brown or blue-black stainings seen in chronic pulmonary hyperæmias. Further views sustaining the affirmative side of the case came from Fuehrer,<sup>20</sup> in 1854; and he now added to our treasury of knowledge by describing "insular bronchitis" (or, as we should call it to-day, "broncho-pneumonia,") one of the principal forms of organic lung disease. (There is good reason to suppose that gummy tumor of the lung occurs at first under the guise of a broncho-pneumonic focus. T. E. S.) Next, perhaps, came Wagner,<sup>21</sup> who added a large number of corroborative cases.

One of the most careful analyses of such cases was made by Moxon.<sup>22</sup> In an elaborate article he gave a review of visceral syphilis as seen by him at the bedside and on the post-mortem table, his object being to show the relative frequency with which the visceral organs are attacked. But as he did not inform us positively that tubercular phthisis was *absent* in these cases, the value of his statistics is practically *nil*, so far as we are concerned; for, of course, the two diseases, tubercular phthisis and constitutional syphilis frequently coexist.

In 1871, Walshe, in his well-known work, "Diseases of the Lungs" (London), wrote of pulmonary syphilis, admitting that in a case cited, a proper diagnosis

was not made until the later history of the patient disclosed the truth to him; but he thought the diagnosis could be framed in such cases by noting the disproportion between the physical signs and the severity of the malady; by a unilateral bronchitis; by either the slight character of the night sweats, or their absence; and by the results of specific medication.

Following Walshe, came Greenfield,<sup>23</sup> who gave the clinical and post-mortem data of twenty-two cases that he had observed in hospital practice, where the liver was affected in twelve, the larynx or trachea in five, and the lungs in eight (the writer believes that this figure should be three). Among the clinical signs, he mentioned a decided tendency to profuse hæmoptysis, attributable to the great vascularity of the new connective tissue. Such an explanation would, of course, only apply to the formative stage of the fibroid induration of the lungs.

Other writers, among whom may be mentioned Cabe and Schnitzler, have written on the subject in the German periodicals. In our own country we have had excellent matter from Van Buren and Keyes,<sup>24</sup> Bumstead and Taylor,<sup>25</sup> Tiffany,<sup>26</sup> Hyde,<sup>27</sup> and Bruen,<sup>28</sup> while Porter has laid down rules for positive diagnosis that have attracted general attention.<sup>29</sup> Porter lays stress upon the following physical signs. He says: "On inspection there is a varying degree of supra- and sub-clavicular retraction and dyspnoea. Palpation is often negative, with perhaps a slight increase in vocal fremitus. On percussion, marked dullness over the affected parts; on auscultation, prolonged and high-pitched inspiratory murmurs, with a decided interruption or pause between it and the expiratory murmur, which is prolonged and high-pitched. The pitch is higher in inspiration and expiration than in emphysema; almost total absence of sibilant or sonorous râles; also of the crepitant and sub-crepitant; very pronounced vocal fremitus on counting." He regards this peculiar respiration without râles with abundant sputum, with a marked tenderness over the sternum, as *almost* pathognomonic of pulmonary syphilis. Dr. Porter, as almost all writers, limits the points of differential diagnosis to the condition of fibroid induration where there are no appreciable cavities. Such a case it was my privilege to see with Dr. Porter quite recently, from the practice of Dr. Zeh; and the diagnosis of syphilitic phthisis made before death, was strengthened at post-mortem examination by the general signs of visceral syphilis in the lungs and liver; while a subsequent microscopic examination of the diseased lung tissue failed to disclose any tubercle bacilli. In this case the miliary deposit in the lungs could not be distinguished from that of tuberculosis by the naked eye.

Let us first review the pathological evidence that supports the theory of syphilitic phthisis:

(1) We often find in the lung a peculiar tumor known as "the gummy," small and yellowish in color, sticky to the feel, and sharply defined from the surrounding tissue. It is a recognized lesion of tertiary syphilis, and forms one of the most common deposits in the liver or kidneys, and is more prominent in the middle or lower lobes of the lung than elsewhere.

<sup>29</sup> Post-Graduate Bulletin.

Similar deposits are almost always found in the liver, or traces of them.

(2) In another class of cases we may have appearances that simulate those of miliary tuberculosis, but perhaps without the so-called tubercular bacilli.

(3) In another class, which is presumably an advanced stage of the miliary formation, we have the peculiar fibroid induration already spoken of, and which is the most characteristic of the syphilitic lesions, and one whose clinical signs have a certain amount of positiveness about them. At first the indurated fibrous tissue has a pellucid bluish appearance, but later on is white and glistening.

(4) If the miliary deposits aggregate and soften as they will do in case treatment is not successful, cavities will form, and they will be found first in the apices, just as in tubercular phthisis. But the cavities are usually small, and if we are slipshod in our diagnosis, the case will pass for a fibroid phthisis (tuberculosis).

(5) Associated with these intra-pulmonary changes will be an unusual amount of fibrous pleurisy, for this is a natural concomitant of pulmonary syphilis, and may, therefore, be expected. Pleuritic effusions are also comparatively frequent.

Now, while there are none of these lesions except the gummy tumor, that are positively determinable at the post-mortem table; still in conjunction with the patient's history, his physical signs and the microscopic examination of the sputum (or of lung tissue after death), the diagnosis may be made with a remarkable degree of certainty, as I shall show in another place.

There is no doubt that lung syphilis is comparatively uncommon, even in general and visceral syphilis, and my observations agree in the main with those of Greenfield and Goodhart on this point. A fair idea of my experience can be gathered from my private pathological and clinical memoranda. Thus, I have found that where there are full clinical and pathological data, the figures stand as follows: In 95 patients that came to the post-mortem table with supposed tubercular phthisis, 12 had evidences of syphilis in their lungs (13 per cent.). Of these 12 cases, six were selected by me as pure examples of syphilitic phthisis (six per cent.). Of the remaining six cases, it was possible and indeed probable that tubercular phthisis was a concurrent lesion (six per cent.). Hence it would appear that syphilis of the lungs is quite as often associated with tubercular phthisis, as that it is the single lesion.

From my clinical records at the Post-Graduate School, I have also taken the following: Of a first series of 392 cases of all kinds coming to my medical clinic, 31 had pulmonary phthisis in some form or other (eight per cent.). Of this same total of 392, 23 were known to have constitutional syphilis (six per cent.). Of this same total of 392, three had lung syphilis (about one per cent. in round numbers). Again, of a second series of 242 cases in all, there were 21 cases of pulmonary phthisis (nine per cent.). Of this total of 242, eight were known to have constitutional syphilis (about three per cent.) while three had lung syphilis (about one per cent.). In a third series of 288 cases, there were 13 examples of ordinary phthisis (15 per cent.). Of these 288 cases, 15 had constitutional syphilis (five per cent.). Of these 15, eight had lung syphilis (or from two to three per cent., of the whole number).

We see then, from these memoranda that in a New York medical clinic, constitutional syphilis may be detected in from five to six per cent. of all the cases. But owing to the inaccuracy with which records are apt to be kept (even under the most rigid scrutiny), we may assume that these percentages do not fairly represent the actual status, and that constitutional syphilis is a much more frequent disease. In my private records, it represents about ten per cent. of all business, hence it is proper to infer that constitutional syphilis is fairly common, and must form a considerable part of the business of every general practitioner. Now, if we add together all the phthisical cases in my clinical records, we find that the number happens to be 95, and this happens to be the number of phthisical cases of which, as already seen, I have full hospital memoranda.

Let us compare these two sets of cases together, and see how much difference is to be found between ante-mortem and post-mortem diagnoses. Of the 95 phthisical cases that came to the post-mortem table in my hospital practice, 12 had lung syphilis (or 12.6 per cent.), while of the 95 phthisical cases that came to my clinic, 14 were put down as having lung syphilis (or 14.7 per cent.), a difference of only from two to three per cent. I hope subsequent observation will not find that the close similarity in results has not been a mere coincidence.

It is not so easy, however, to determine the part that syphilis of the lungs may play in inherited phthisis, in the matter of clinical history. That it has an important relation I feel assured from personal experience at the bedside; but we have yet to establish the exact relation between the two. Some things are apparent. Thus, take the case of a man suffering from a severe form of progressive syphilis, he becomes greatly deteriorated in health, and therefore a fit subject for the development of tuberculosis, if other conditions favor. In such persons the two diseases may develop side by side, each intensifying the other. Again, from a pathological point of view, in the early stage of both diseases, there are the same catarrhal features, and in the farther progress of the disease the same tendency to thickening and degeneration of vessels, implication of lymphatics and the production (in certain types) of an imperfect form of fibroid tissue, much as in fibroid tuberculosis. As to the microscopic character of the tubercle, so good an observer as Goodhart failed to find any difference between them, and others have sustained this view.

(To be continued.)

## PISTOL-SHOT WOUNDS OF THE SKULL<sup>1</sup>

BY E. H. BRADFORD, M.D.,  
Surgeon to the Boston City Hospital.

THE surgeon in civil life has occasionally presented to him the problem of treatment of pistol-shot wounds of the brain. These, fortunately, are not of very common occurrence, and those who happen to be connected with the large general hospitals of cities, are the surgeons who are more frequently required to face the question of the proper surgical treatment in these cases. If he endeavors to prepare himself by a reference to the standard works on the subject, he will find

<sup>1</sup> Read before the Boston Society for Medical Improvement, March 9, 1891.

but little guidance, as statistics are chiefly taken from military surgery where the missiles are rifle bullets or of comparatively larger calibre than is common in civil life. The question is one of importance and demands judgment, experience and knowledge; and ordinarily the experience of any one man in this class of surgery is necessarily limited. As the majority of these cases are the result of homicidal intent, their importance is great, for the surgeon is aware that two lives are often at stake, or that the future of two persons depend upon his skill and judgment. The following three cases may serve to call attention to the variety of conditions presented in this class of accidents when brought for treatment.

**CASE I.** Man with suicidal intent shot himself in the right forehead. The patient was thoroughly unconscious, with stertorous breathing, the pupils did not react, and beyond certain voluntary movements the patient seemed entirely paralyzed. No treatment was undertaken, and the patient died in four hours.

**CASE II.** A healthy man was assaulted by unknown assailants, and found in an unconscious condition, with a pistol-shot wound in the right forehead. He was unconscious. The wound in the head was a small opening, filled with clotted blood, there being no bleeding. The wound was cut down upon, and the scalp dissected off. On removing the scalp a great deal of clotted blood exuded, and there was found to be a copious hæmorrhage. The skull was trephined and the opening in the dura enlarged, and a good deal of hæmorrhage found to proceed from the opening. The wound was irrigated and thorough drainage ensued. The patient died in twenty-four hours.

**CASE III.** Similar to the above, except that the patient was conscious. A healthy man received a bullet-wound, at short range, on the temporal region. The man was conscious, but there appeared to be evidences of bleeding. The scalp was marked with grains of powder. Examinations with the probe would indicate that the bone was fractured. An incision was made, the flap reflected, and the bone found lying in a wound through the skull, which was penetrated. Singularly, the bullet was found with the butt end toward the inner side of the cranium; in other words, the bullet, as it struck the skull, had fractured it, but the penetrating power was not sufficient to do more than make a hole. It had turned a complete half-revolution, so that its butt lay where the point hit. The bullet was removed, and the patient made a good recovery. The calibre of the pistol was said to be twenty-eight.

In the present state of surgical knowledge on the subject, precise rules of action have not yet been formulated and I venture to suggest a discussion of the subject by the Society, making as a prelude to suggestions for the discussion an attempt at generalization.

In cases where the patients are moribund, it is manifestly useless to intervene, as surgical interference is necessarily meddlesome and unwise. But it is not the part of surgery to regard patients as moribund where there is the slightest chance of recovery, and the question which surgical instinct prompts the true surgeon to consider is whether the chance for life, which every living patient may be presumed to have, is to be injured or is to be improved by any surgical interference; this question involves the consideration of the present modes of treatment; the expectant, the radical (including trephining); probing of the wound; and

attempts to remove the foreign body from the cranial cavity.

Wherever there is a reason to believe that there are fragments of bone pressing upon the cortical surface of the brain, it is manifestly desirable to attempt to remove these; and for that reason, in all cases where the bone seems splintered, especially if the patients are conscious, the indications are that the skin flaps should be dissected up, the cranial injury explored, and loose fragments removed, the wound being cleaned. Where the dura is opened and there are penetrating or perforating pistol-shot wounds of the skull, the question is less simple. The patients are usually unconscious and death is imminent. In a large majority of these cases death occurs. The exact percentage of mortality, it is difficult to determine, as our statistics are taken chiefly from battle-fields and from military practice. The greater proportion of penetrating rifle-shot wounds of the skull causes instant death. Of those, however, who do not die immediately, a certain percentage recover; and a number of instances where complete recovery has taken place after a penetrating rifle-shot wound of the skull, are well authenticated. These cases have been recorded by the older surgeons, and a number of instances are recorded during our war, the histories having been watched carefully by the Pension Department; and it may be taken to be certain that penetrating pistol-shot wounds of the skull are by no means necessarily fatal. Statistics vary as to the value of trephining in these cases. If the statistics are examined, it will be seen that they point to a greater percentage of recovery where trephining has been used than where trephining has not been used; but a moment's consideration would show that this method of using statistics is necessarily fallacious. For in a majority of cases where trephining is not attempted, the patients have been considered too severely injured for the operation, as the cases where trephining was undertaken represent those which in the opinion of the surgeons were able to withstand the shock, and presented some hopes for eventual recovery. Furthermore, the different localization of the pistol-shot wounds will give a different percentage of mortality. And for this reason, unless it is known in our table what portion of the brain was wounded, no figures can be of sufficient value to justify extensive generalization. Under these circumstances and until better and more carefully considered statistics have been collected, treatment must be based upon the general principles of surgery. The opening of the dura is a procedure which should not be undertaken rashly; but if the dura has been penetrated by a bullet, it is certain that the injury to the brain substance which follows, may in a certain number of instances be accompanied by an effusion of blood. Where there is effusion of blood, it is desirable that there should be no increase in pressure in the brain, and for this reason it would be desirable to enlarge the opening of the dura to give a chance of escape to the fluids collected below. It is a pathological fact that the wound in the dura is smaller than the calibre of the bullet, and in many instances this is sealed by a blood clot, so that an effusion of blood may take place under this, causing cerebral compression.

The question, then, is one of surgical judgment, with the possibility of error in a large number of cases. In the present system of imperfect means of localization it is almost impossible to determine

whether the bullet remains in the centre of the cerebral tissues, or whether it lies within reach. It is, therefore, impossible to determine the position of the bullet without the use of the probe, and even with the probe the danger is that greater injury should be done to the brain substance by the examining instrument than good would be accomplished by its discovery. For this reason it would seem to the writer to be advisable to discountenance all probing of the cerebral tissue for bullets, from the fact that it is known that no great harm comes from the simple presence of the bullet alone. The same is true in regard to the presence of hair, or pieces of the cap or hat. Where the wound is a large one and the brain tissue lacerated, careful irrigation with boiled water would seem to be the best way of managing the lesion, and that no attempt to extract foreign bodies imbedded at any depth in the tissue of the brain, is surgical or desirable.

The subject can be summed as follows: In penetrating pistol-shot wounds of the skull, death is to be anticipated in a large majority of cases. Recovery, however, does occur in a certain number of instances. The treatment should be the treatment of a penetrating fracture of the skull (that is, a fracture from any sharp instrument, a nail or spike). The scalp should be dissected away from the injury and the bone thoroughly examined. Loose fragments of bone should be removed. A trephine should be used if it is considered necessary to thoroughly cleanse the wound or to give egress to any collection of fluid or blood that may be below the dura. If the dura is penetrated and if there is any bulging of the dura, the dural opening should be enlarged. The brain substance should be thoroughly irrigated and washed, but not probed or treated with violence. It is unnecessary to state that the strictest asepsis is desirable.

### COELIOTOMY FOR RUPTURE OF THE UTERUS DURING LABOR.<sup>1</sup>

BY H. C. COE, M.D., OF NEW YORK.

ALTHOUGH the literature of this subject is quite exhaustive, most authors deal with the etiology and pathology of rupture of the uterus rather than with the treatment; and much of the teaching with regard to the latter antedates the era of modern abdominal surgery. The writer feels some hesitation in writing upon this theme, as it has been already ably presented to the American Medical Association by Dr. William H. Wathen and Dr. C. A. L. Reed, in papers read before the Obstetrical Section. The writer's purpose in reintroducing the subject before the Surgical Section is to have it discussed from the broad stand-point of general surgery. This is entirely proper, since rupture of the uterus is to be considered in the same light as a rupture or other lesions of any other of the abdominal viscera. It is pre-eminently a surgical emergency, and should not be studied from its gynecological or obstetrical side alone.

When Lawson Tait feels justified in proposing Porro's operation as the proper treatment for placenta previa, we may well ask, Is simple expectant treatment applicable to the far more formidable obstetrical complication, rupture of the uterus? Note

that the paper deals with rupture of the *parturient* uterus, and not with injuries of the organ before labor. This is an important distinction to be borne in mind in the discussion. The writer bases his paper entirely upon his personal experience,—that of four cases (seen within a period of eighteen months) in which abdominal section was performed. One case was successful, the patient being now in perfect health.

CASE I. Rupture due to undue interference in the first stage (forceps and attempted version), the child being of unusual size. Operation two hours after the accident, the patient being in collapse from active internal hemorrhage. The child's head had escaped from the rent, which extended from the cervix through the left broad ligament, half-way to the fundus. Child extracted through the rent, after application of rubber cord. Uterus removed, and pedicle treated by the extra-peritoneal method; on account of extensive laceration the entire stump sloughed out, but the patient made a good recovery.

CASE II. Cause of lesion identical with that in Case I. The injury was not recognized until twenty-four hours after the birth of the child, when the patient was already septic. Coeliotomy was performed. Transverse tear on posterior aspect four inches long, in lower segment, with commencing peritonitis. The rent was sutured, and thorough irrigation and drainage established. Death took place from shock twelve hours later.

CASE III. Moderate contraction of anterior conjugate, with large child. High forceps application was unsuccessful. Delivery was accomplished after difficult version. In removing an adherent placenta the accoucheur withdrew a coil of small intestine, which prolapsed through a rent in the posterior wall of the uterus. It was replaced (as was supposed), and the opening was plugged with iodoform gauze. Abdominal section was then regarded as unjustifiable on account of profound collapse. The writer saw the patient eighteen hours later, and found her in fair condition, the upper portion of the vagina being filled with intestine. He proposed and performed coeliotomy at once. There was a transverse tear posteriorly in the lower segment, extending from between the bases of the broad ligaments. It was too extensive to suture, so both broad ligaments were clamped, and the uterus was extirpated *in toto* in five minutes. It was found that the intestine had not been replaced, but had been nipped in the edges of the rent, so that at least three feet were black and gangrenous. Irrigation and gauze drainage per vaginam. Death from shock ten hours later.

CASE IV. Spontaneous rupture during normal labor, not recognized. Collapse five hours later, but no external hemorrhage. The writer saw the patient twelve hours after the accident, and diagnosed rupture of the uterus with internal bleeding. A consultation was held, and the unanimous opinion was that there was an extensive laceration into the left broad ligament, and that active hemorrhage was in progress, which it was necessary to arrest. There was doubt as to whether the rent extended into the peritoneal cavity or not. Exploration advised. This was conducted rapidly. No blood found in the abdominal or pelvic cavity. There was an immense hematoma of the left broad ligament, extending upwards into the corresponding iliac fossa. The abdom-

<sup>1</sup> Abstract of a paper presented at the Annual Meeting of the American Medical Association, May 5, 1891.

inal wound was closed and the vagina tamponed with gauze, although there had not been any external hemorrhage whatever. Death from shock.

Many cases of spontaneous rupture are doubtless unrecognized by the general practitioner. Profound shock after delivery should always awaken suspicion, even if there is only moderate external hemorrhage; and a thorough examination should be made. Text-books give rules for recognizing rupture only during parturition.

The rules laid down for the treatment of rupture are uncertain and confusing. The tendency of the practitioner is towards purely expectant treatment. He would perhaps pack the vagina with gauze, and wait. This course is too often fatal. The emergency is a surgical one, and is to be treated according to the ordinary rules of surgery. The fact that successful cases of celiotomy for rupture of the parturient uterus are comparatively rare is no more an argument against the operation than if it were applied to gun-shot wounds of the abdominal viscera.

In analyzing the unsuccessful cases it will generally be found that the operative interference came too late, that is, from eight to eighteen hours after rupture. The writer's successful case was as unfavorable as could be imagined, but the patient was operated upon promptly, as soon as the lesion was discovered. Two methods of active treatment are now recognized and practised, namely:

(1) Drainage per vaginam.

(2) Abdominal section, followed by either (a) drainage, (b) suture of the tear, or (c) amputation of the uterus. Simple drainage has some powerful supporters (mainly in the Vienna school), and the statistics are apparently convincing; but it is not capable of general application to all cases, and the indications are not always clear, because without opening the abdomen it is frequently impossible to determine the following important points: (1) the nature and extent of the tear; (2) the presence of active hemorrhage; (3) the presence of blood and amniotic fluid in the peritoneal cavity.

The writer thinks that abdominal section is indicated under the following conditions:

(1) Before the uterus is emptied. (a) When the placenta or any portion of the fetus has escaped through the rent, attempts at manual delivery only increase existing shock and destroy the patient's chances after section, as invariably shown by records of unsuccessful cases. (b) Where there is evidence of progressive internal hemorrhage.

(2) After the uterus is emptied. (a) When there is extensive prolapse of the gut through the tear; (b) in all complete lacerations (especially in those involving the broad ligament), except small tears low down near the vaginal fornix, where good drainage can be maintained; (c) in incomplete tears in which the broad ligament is extensively involved, and there is evidence of progressive hemorrhage.

Parvin's summary is a comprehensive one, namely: "Probably the solution of the question is this, that where the tear is in such a position that vaginal drainage is perfect, the abdomen need not be opened; but, if such drainage is impossible or imperfect, then section is indicated."

What shall we do after opening the abdomen?

(1) Arrest hemorrhage, either with forceps or the temporary rubber ligature.

(2) If the tear is small (two inches) and is low down in Douglas's pouch, drainage per vaginam may be indicated.

(3) If the tear is clean-cut, without contusion of the edges, and does not involve the cervix or broad ligaments, it may be closed with deep and sero-serous sutures.

(4) If the tear is not low down, is extensive, with contusion of the edges, and especially if a portion of the fetus protrudes, amputation of the uterus, with extra-peritoneal treatment of the stump is indicated.

(5) In extensive transverse tears in the lower segment, and in tears beginning in the cervix and extending upwards through the broad ligament, the writer would strongly urge the propriety of total extirpation of the uterus as the operation *par excellence* (as it is in many cases of hysteromyomectomy), for the following reasons: (a) It requires less time than Porro's operation, and is quite as easy, especially if the patient is placed in Trendelenburg's posture. There should be no great shock or loss of blood. (b) All the contused tissue is removed, which if left behind in the stump, will inevitably slough and imperil the life of the patient. (c) Drainage is perfect, and after thorough irrigation and toilet of the peritoneal cavity, it can be closed, drainage being maintained per vaginam with iodoform gauze, as after vaginal hysterectomy.

In conclusion, the writer deprecates any intention of recommending a heroic method of treatment to the entire exclusion of a more conservative one. He is an avowed conservative in abdominal surgery, but believes that rupture of the parturient uterus is a desperate emergency, in which a fatal termination is the rule, and that it requires prompt and energetic treatment, according to the rule of modern surgery. The fact that the statistics of celiotomy in these cases has shown a large mortality, is not an argument against the operation. In every case the accoucheur, if not himself a surgeon, should, without an instant's delay, summon experienced counsel and explain to the family that immediate resort to abdominal section may be necessary, as only by prompt interference can we improve statistics, and thus elevate the operation above the level of a hopeless and apparently unnecessary surgical experiment.

## Clinical Department.

### A FIVE-INCH HAIR-PIN IN THE RIGHT POSTERIOR NARES.

BY M. W. KELLNER, M.D., FAULTON, R. I.

ON Thursday, May 28, 1891, I was called to see Margaret B., age twenty. She said that the day previous, while dressing, she swallowed a pin. She had been to three physicians, and was informed that it was imagination on her part. I, too, thought that imagination was her highest prerogative. She insisted, however, that she had swallowed a pin, and thought she had felt it in the "back part of her nose." I asked in regard to the size of the pin, and was informed that it was a regular sized hair-pin. I now felt more incredulous than before. However, I inserted a probe into the right nostril, and found that there was a foreign body in the right posterior nares. I was able to find one rib of the hair-pin, but the end was inserted

into the mucous membrane of the nasal bone. I finally secured a firm hold with a long, slender forceps and made traction. I succeeded in getting one rib of the hair-pin about one-half inch through the right anterior nares, when, in the meantime, the other rib projected through the right nasal bone close to the inner canthus of the right eye. I then pulled the hair-pin through the nostril. The hair-pin measured about five inches from point to point.

## Reports of Societies.

### BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

G. G. SEARS, M.D., SECRETARY.

REGULAR meeting, Monday, March 9, 1891, the President, DR. FREDERICK I. KNIGHT, in the chair.

#### ORAL COMMUNICATIONS.

DR. BAKER alluded to a statement made at a previous meeting of the Society to the effect that Dr. Keith had relinquished the Apostoli method for the treatment of uterine fibroids, and in order to correct that statement read from a pamphlet by Dr. Keith, published in January, 1891, the following extracts:

"The result of experience amounts to this: During the last three years and a half I have got along without a single hysterectomy in soft or solid fibroids."

"This treatment *almost always* relieves pain. It *almost always* brings about diminution of the tumor, sometimes rapidly. It *almost always* stops hemorrhage, sometimes rapidly."

"The results are *almost always* permanent, and the growth of the tumor, if it be not lessened, is stopped. The general health is immensely improved."

"By *almost always*, I mean nineteen cases out of every twenty."

DR. KNAPP showed

#### A CASE OF ASTASIA-ABASIA.

DR. E. H. BRADFORD read a paper on

#### BULLET-WOUNDS IN THE HEAD: SHALL THEY BE OPERATED UPON?

DR. CHEEVER: I never extracted a bullet from the brain, and I know of one case where I am positive one is lodged in the brain and has not produced any very serious symptoms. A young school-girl was sitting in a swing, swinging in the garden. Some young men were firing at a mark on the hillside near by with a rifle. The ball struck a tree and glanced and came down and struck her on the forehead just above the eyes. She walked to the house, and soon became unconscious. Soon afterwards I saw her, and she was still unconscious. The wound seemed to be at the upper part of the frontal sinus. The scalp was incised, and the outer wall of the frontal sinus was found bent inwards, and that was picked out; and then it was found that the inner wall of the sinus was bent inwards down on the membranes of the brain, and to relieve that the inner wall, and the outer wall partially, were trephined and a number of fragments picked out, and then the wound was found to be just about opposite the division of the falx. The membrane seemed to be injured. Perhaps injudiciously,

at any rate I did put a probe in beside the falx and pass it down several inches and found nothing, and then the case was let alone. The patient recovered perfectly, apparently. After a while she returned to her usual duties, but came to see me several times a year or two afterwards, and, as far as I know, had no symptoms in consequence. It would seem to be impossible to conceive of any other place that the ball could have been except in the brain, owing to the direction of the bony fragments and the fact that both tables were perforated. I thought it was lying somewhere on the tentorium.

In the case I reported the other night of the little girl who was shot in the ear, the ball lodged on the petrous portion of the temporal bone and was discharged through the mouth. It is very doubtful whether the brain cavity was opened, but the temporal cavity was shot through.

It seems to me Dr. Bradford has stated the case pretty correctly when he considers these like the punctured depressed fractures from other causes. The punctured depressed fracture is one of the most dangerous we have to deal with, because the inner table is brittle and the fragments lie rough on the dura mater, and if not removed give rise to meningitis.

I remember the cases of several persons who came to the hospital after receiving fractures from spikes, etc., falling from great distances. The patients could hardly be persuaded to submit to operation. In proof of what could take place, if this was not done promptly, I have a parallel case in the practice of another, where the punctured depressed fracture existed in all its typical phenomena. The patient came to the hospital, but refused operation. At the end of a week the patient had unequal pupils, restlessness and fever, and commencing meningitis. At that time his friends consented to operation. He was trephined, and the condition of the inner table was found with loose spiculae, and he made a slow recovery, but he finally got well.

It would seem that if a pistol-ball goes through the head and gets into the brain, unless it take some of the bony case of the skull through with it, it could hardly carry in any foreign substance with it. The ball goes in of itself; the cartridge is left behind of course. This would seem to be a case where what enters the brain cavity beyond the spiculae of the skull can be nothing but the leaden ball. The leaden ball is known to be comparatively innocuous if it can be encysted. It depends upon how much it has lacerated the brain, and whether it will lie where it will not do any harm. To extract it would be extremely difficult. I fancy the cases where balls have been extracted from the brain are few; and I am inclined to think it is right to explore these injuries, treat them antiseptically, treat them as you would the punctured depressed fracture, and, as a rule, to go no further. I should think that was the conclusion to which we must come in our present state of knowledge about brain surgery.

DR. HARRIS: It has occurred to me that one of the reasons why surgeons were slow to interfere in cases of penetrating wounds of the skull, especially if they were homicidal, was that they would be liable to annoyance on the witness-stand, and it might be claimed that they had contributed to the death by the interference in such case. That would have no bearing medicolegally, for the law would hold that the person guilty of inflicting the wound was guilty just the same, be-

cause he had no business to put the patient into a condition where the question of operation or non-operation would have to be decided. And practically it comes to the same thing whether he operates or not, because the same question might be raised if he treated the case, that he was responsible for not operating where operation might have done good. Of course the cases that have come under my personal observation have been cases where the wound has been fatal. In none of these cases does it seem to me that an operation would have, although some of the patients have lived twenty-four hours or more, varied the result.

In the first place, about localizing the ball. There is nothing that has so many vagaries as a bullet in its course in the body. I remember the last case of shooting I had occasion to examine. The section showed that the ball had encountered only soft parts; but it is, perhaps, as curious as the case Dr. Bradford related, for this ball, entering the chest near the nipple, striking no bone, went through the lung, penetrating the pericardium, striking the heart, bruised it a distance of one and a half inches, then went again through the pericardium, through the diaphragm, entered the stomach, came out, again pierced the diaphragm, and lodged in the base of the lung. In the case of the skull, however, the ball is carried very nearly in a straight line from side to side or from before backwards. In all the cases I have seen it not only ploughed a furrow through the brain substance itself, but it had left foreign matter along its track, carried along spiculae of bone from the inner table of the skull and left little fragments of itself, marking its course in the brain with little fragments of lead along the whole line, so that if the bullet could be located, and the patient trephined, and the ball removed, there still would remain, in spite of any treatment I can see, little fragments of foreign substance in the brain, which would be more likely than not to set up an inflammation in the brain. At the same time, with the almost inevitable consequence of death from such a wound from non-interference, it seems to me that any possible chance that the patient can have is a thing to be considered, and the great difficulty would seem to me surgically to be in locating the ball. Probably in these cases where the ball goes into the skull it makes the same round hole that it does in going into a piece of board. When it comes out its wound of exit is like the wound of exit of the bullet going out of a board or plank. As it enters the dura, however, the bullet does not make as large a hole as itself when the wound is viewed subsequently, because it not only penetrates, it stretches, and from such opening there would not be sufficient drainage, it seems to me, and if you are going to do anything at all you must enlarge the opening either to extract the ball or to get a sufficient amount of free drainage.

The location of a ball will depend a great deal upon the cartridge, the amount of powder used, and the size of the ball. As a rule, the small balls of the twenty-two calibre have to be placed in very close proximity to the skull to penetrate it. The larger balls of thirty-two calibre and upwards have so much force, if they are fired anywhere near the skull, they not only penetrate, but do not lodge on the dura, but go clear through and lodge on the opposite side of the skull. It therefore seems to me to be extremely difficult to locate the ball with sufficient certainty to trephine.

DR. CAROT: The only gun-shot wounds I have seen

of the head have been where the bullet entered in the face or the auditory canal, without evidence that the skull was penetrated, and where the subsequent course of events showed that it was not. It seems to me that Dr. Bradford's comparison of these wounds to one made by any penetrating substance like a sharp piece of iron making a punctured wound in the skull is a good one. The importance of drainage we all know. The importance of removing spiculae of bone which project into the dura or press upon it in these punctured wounds we all know. Also in making an operation to obtain these benefits we may have the good fortune, which Dr. Bradford had, of finding the bullet caught by the tough dura, where it could be removed. Where the bullet has actually penetrated the dura it seems to me that all probing of the brain is meddlesome and likely to do harm. I was very much interested in hearing what Dr. Harris said about the little fragments of lead along the track of the bullet, because that would add another reason to my thinking so. The possibility of finding a bullet after it is once in the brain is very slight; and the chance of harm from the bullet seems to me less than the chance of injury by extensive probing and hunting for it. If there is no evidence of considerable hæmorrhage inside of the dura, I think I should disagree with Dr. Harris as to the importance of enlarging the hole through the dura. Without evidence of compression of the brain or hæmorrhage inside, I would prefer to leave the blood to fill the track of the ball, and to heal as we constantly see wounds on the surface healing by blood clot.

We may secondarily in these cases have symptoms of a localizing character. The position of pressure or irritation in the brain may be subsequently localized by symptoms of irritation, such as convulsive attacks in motor groups of muscles, and we may be thus aided in locating a bullet which could not have been found by the probe, and to successfully remove it. Of course, in that case the motor symptoms of irritation would show that the bullet was doing harm in the position it occupied, and would make its removal advisable.

DR. BURRELL: I would like to ask Dr. Harris if I understood the actual cause of death to be from hæmorrhage or from meningitis.

DR. HARRIS: In every case I have had but one it has been from shock, which followed very quickly. If life was prolonged twenty-four hours, it was from meningitis.

DR. NEWELL: I believe I have happened to make a special study of this subject; and I should like to say that Dr. Bradford has given what I believe to be the ideal rule for treatment in these cases. The discussion is limited to bullet-wounds of the brain, so I will not speak in regard to anything else. The greatest student, perhaps, of bullet-wounds has been Réclus, of Paris. I do not quite agree with him in stating that all surgeons at present do not interfere with bullet-wounds of the cranial, abdominal or thoracic cavities. It seems to me the rule is getting gradually established, not to explore for the results of a bullet-wound if the ball enters the thoracic cavity. As far as the cranial cavity is concerned, I think it depends a great deal on the individual case. In Dr. Bradford's case he found the bullet, although it was fired at the shortest possible range, superficially located. The element Dr. Harris referred to, the amount of powder, had not been able to send the bullet, at the shortest possible range, through the skull. I think, as far as

the records of the War of the Rebellion are concerned, that they are practically valueless in considering the treatment of bullet-wounds. We know, that, if they had had the wound in the abdominal cavity, or any other cavity, at that time, they would not have thought of going in and hunting for it, because the usual result was pyæmia or septicæmia. What I would like to lay stress upon is, that there is one great fallacy in a certain method of bullet-wound treatment, and that is in laying stress upon the importance of the location of the bullet. I think this is primarily not of the least importance. The leaden bullet is perhaps sterilized by its rapid passage and the development of high temperature in the passage from the pistol or rifle. There is no end of cases that prove to a certainty, that under ordinary conditions a bullet is perfectly harmless; its location is of no importance. The only thing of importance in the skull, I think, is what the bullet has done. If it has smashed a great plate of bone and carried it with it, a man should not busy himself with where the ball is lying. I don't think any apparatus to determine the location of the bullet, telephonic or otherwise, is of the least value whatever, except as it might come into use with secondary symptoms. And now, if it is not boring the Society too much, I would like to read one or two quotations from eminent surgeons, in the summing up of a certain case showing the innocuousness of a bullet under ordinary circumstances.

"The patient died of septic infection of the blood. It was blood-poisoning, whether called pyæmia or septicæmia.

"The source of this infection is the subject of inquiry.

"The ball entered the body on the right side, at a point three inches and a half from the spinous process of the first lumbar vertebra. It fractured the eleventh rib, was then deflected downward, fracturing the twelfth rib, and passed across the axis of the body through the spinal column, in front of the spinal cord. It fractured the body of the first lumbar vertebra, and drove a number of small fragments into the adjacent soft parts. And it lodged about two inches and a half to the left of the spine, below the pancreas and behind the peritonæum, where it was found completely encysted."

"The post-mortem showed that the ball was, and had been for a long time, completely encysted. It was, therefore, harmless, and must be eliminated from the list of agencies supposed to have produced the septic condition of the blood."

In reference to the location of the bullet being a matter of no importance whatever, I might state that later on it becomes of secondary importance, as Dr. Cabot suggests, when he speaks of an abscess. Of course an abscess forming would be not a primary condition but a secondary one, and there, as he stated, the indications would point strongly to acting at once. There would be no doubt about the propriety of operating to relieve that condition. I have gone through perhaps as large a number of cases as any one of bullet-wound, because I have read through and glanced through about all that have been reported and indexed up to 1888, and four or five years previous to that. As Dr. Bradford lays down the rule, I think we should take it for granted that the location of the bullet is an insignificant matter and treat the wound so that every chance for drainage is offered. The wound, if suc-

cessfully antiseptized, is as safe as a subcutaneous wound unless the bullet has carried in any septic material to give rise to harm. The matter of the rubbing off of lead on the brain tissues shows the peculiar nature of bullet-wounds, that they are not to be compared with any other wounds. We cannot conceive how a comparatively hard bullet should rub against soft tissues and rub off lead. I have seen the reports of autopsies where the bullet had gone through the lung and no cicatrix of any kind could be found in the lung. The bullet goes perhaps in the same way as a pin through a bubble without bursting it — the rapidity with which it does its work being a strong factor in the result. It may go through a structure and scarcely leave a trace.

DR. KNAPP: I have been very much interested in Dr. Bradford's advice on the subject, because two or three weeks ago I was called out of town to see a young man who shot himself in the head with a thirty-two calibre bullet while playing with a revolver. I know, of course, little about pistol-shot wounds. I have seen a few cases at the hospital in consultation with the surgeons. I was asked to see this patient with the idea of localizing the bullet so that the surgeon might operate and remove it. I found a young man about eighteen years of age with the opening of a pistol-shot wound about an inch above the external angle of the orbit on the right side. He had been playing with the pistol, holding it up, and it had probably gone off while pointed obliquely at the forehead. He was semiconscious, but he would occasionally answer. He moved his eyes, his arms and his legs, and seemed to feel a touch or a prick. He would occasionally answer a question, but I could not make out whether he saw. He certainly heard. There was nothing abnormal about the reflexes. I said that I did not know where the bullet was. I held that it was entirely impossible to say where it was from any symptoms, that the general disturbance of the brain had been such that it was entirely impossible, and would be in any case entirely impossible to separate the symptoms caused by the passage of the bullet from those caused by the presence of the bullet. I may say that the bullet in going in had left a fragment on the bone which had been removed, a little seal of lead, and they had probed in to the depth of about an inch into the brain, a little probe going in somewhat diagonally. I said I did not think the presence of the bullet made very much difference now. The bullet was more or less aseptic, and I knew a twenty-two calibre bullet could make a track through the brain, destroying brain matter, for a space an inch in diameter. I could see very little good if they knew where the bullet was in taking it out; the damage had been done by the smashing up of the brain by the bullet, and not by the actual presence of the bullet there now. The boy's condition was pretty poor, and I advised that the hole should be enlarged and opportunity offered for drainage. That was not done. The boy died two days after I saw him. An autopsy was made, and it was found that the bullet passed backwards and went completely through both hemispheres, striking the left parietal bone about an inch back of the parietal eminence, bruising the dura and returning upon itself in its own track.

The result of the autopsy, I think, rather justified my statements that the bullet itself had done a good deal of damage to the brain, and that it could not be

told exactly how much. All that I felt able to say then was, that I did not think it had damaged the motor areas or motor tract very much.

DR. BRADFORD: In the history of the case of President Lincoln there was one fact of pathological interest that is not generally known. The bullet did not pass through the skull, though it penetrated into the cavity. It was arrested half-way in the brain, but there was a fracture of the orbital plates, although the bullet had not reached the orbital plates. The bullet entered the occipital region and carried some fragments of bone part way into the cranial cavity. There has been some discussion as to the cause of this fracture of the orbital plates. The surgeons in charge reported it as a case of fracture by contre-coup, that is the impact of the bullet on the cerebral substance fractured the thin bone of the orbital plates by jar. Longmore, however, believed the fracture due to the general concussion of the cranial osseous structure transmitted from the point of impact to the thin orbital plates.

In regard to the localization of the bullet, I think Dr. Newell may have stated a little more strongly than he meant to, that the bullet could not do any harm. If it would be possible to localize a bullet, and find, as it has been found in one or two cases, that the bullet was impacted on the other side of the scalp, it would be desirable to remove it. Of course, the bullet that enters the skull is a very sharp body as it lies in the skull, and it would be desirable to remove any sharp substance if it could be done without injury.

DR. NEWELL: I think so secondarily. I don't think you would want to explore through a long track primarily. Dr. Gardner claims he can localize a bullet, and, if he can, there may be some value in so doing.

#### THE NEW YORK ACADEMY OF MEDICINE. SECTION ON GENERAL MEDICINE.

STATED Meeting, May 19, 1891, FRANCIS DELAFIELD, M.D., Chairman.

DR. THOMAS E. SATTERTHWAITE read a paper on  
PULMONARY SYPHILIS IN THE ADULT.<sup>1</sup>

DR. ROBERT W. TAYLOR said that when Dr. W. H. Porter read his paper some years ago, and he heard the views expressed by Drs. Delafield and Draper he found himself in a state of considerable doubt and uncertainty on this subject. He therefore resolved to make a careful study of all cases coming within his knowledge that seemed to have any bearing on it. In this connection he would say that in an article by Lancereaux, published in the *Union Médicale* for January, 1891, that author took the ground that it is very difficult to distinguish, even with the microscope, between syphilis of the lung and tuberculous disease, and that the two may go hand in hand together. He recognized two forms of pulmonary syphilis. In the first there was a proliferation of connective tissue around the smaller blood-vessels, which later resulted in fibroid consolidation of the lung. In the second the lesion consisted of a gummy tumor.

Dr. Taylor said that he had seen cases in which pulmonary tuberculosis supervened upon syphilis. One very interesting case he had previously reported, where the patient, suffering from a severe papular syphilide, was supposed to have small-pox, and later

developed tuberculosis and died. At the autopsy the physician making the examination became infected with syphilis from a cut; and this was one of the cases on record in which inoculation took place from a cadaver. He had gone over his records of cases to see what light they would throw on this subject of pulmonary syphilis, and would relate four of them by way of illustration. They were as follows:

CASE I. A gentleman thirty-two years old and in fine health, contracted syphilis early in 1888. He had general exanthemata and mucous lesions, and followed treatment for perhaps six months. He came to me in May, 1890, rather more than two years after infection, having an obstinate syphilitic psoriasis. At this time he was pale and thin, and complained of a slight hacking cough and of pain on breathing, over a patch having an area of three square inches on his side, over the middle lobe of the left lung. He expectorated a little mucus, mostly in the morning. Over the morbid area there was very slight dullness, and rough breathing could be heard. There was no elevation of temperature. He was put upon mixed treatment and syrup of the iodide of iron. Within a month his pain ceased, he coughed less, and he gained strength. In July he weighed more than he ever did in his life, and felt correspondingly well. At this time there was no perceptible lung trouble.

CASE II. A gentleman, twenty-two years old, syphilitic for eighteen months; but had taken no treatment until one year after infection. In May, 1890, he first noticed shortness of breath and a slight cough. Sputum not very copious, mucoid, a little fetid, and occasionally streaked with blood. A physical examination showed dullness over the left side, about the middle of the lower lobe; its area being the size of a lemon. During inspiration large and small râles were heard. He was thin, pale and sallow, and very weak. Under the mixed treatment and iodide of iron he was seemingly entirely cured in July of the same year. Promptly after the beginning of the treatment he began to feel better, and quite rapidly his nutrition became improved; so that he regained his color and flesh. In July, I could not find any abnormalities in the lung. There was at no time any elevation of temperature, though in May the pulse was thin and rapid.

CASE III. A female, married, aged thirty-eight, a blonde of poor fibre, infected with syphilis in October, 1886, came to Charity Hospital in 1887, giving a history of mucous patches in the mouth and vulva, syphilitic rheumatism, and a great falling away in flesh and strength. She was treated energetically, but remained in the hospital only one month. In July, 1887, she came back with diffuse gummatous infiltrations in the fingers and over the body. She was patched up again, and as soon as her lesions healed she went out. In November of the same year she came back again with the following story and the following condition: For a month previously she had had a slight cough, was a little short of breath upon exertion, and noticed that she was more readily fatigued than before. She had not followed the directions given her on leaving the hospital in July, to keep on with medicine and get all the fresh air she could. Being a dress-maker, and the mother of children, she had had to apply herself to the needle for long hours each day. In this state and under such conditions she had been taken, two weeks before coming in, early

<sup>1</sup> See page 573 of the Journal.

one morning with an alarming hæmorrhage (the blood being very dark and thick), which continued free for about an hour, and then kept up in a mild degree all the day. Her general symptoms became worse, and she had three other hæmorrhages of less severity before her admission to the hospital.

We found very slight elevation of temperature (this being more marked in the evening than in the morning), and general prostration. Over the upper lobe of the left lung, extending three inches down from the clavicle, and all the way across the chest, there was marked dullness on percussion, and on auscultation there was heard a whistling noise, mixed with moist râles. Everywhere else the lungs were normal. We put the woman on extra diet, sent her out daily in the warm part of the day, gave her the strong mixed treatment, rubbed the chest every evening with twenty grains of strong mercurial ointment, and sent her home with no appreciable trouble in her lungs, and in a fair state as to flesh and strength, in the middle of January, 1888.

**CASE IV.** In August, 1890, I was asked to see in consultation a man twenty-five years of age, thin, pallid and wan, who had been infected with syphilis in June of that year. He had at the date of examination double syphilitic, hydro-arthritis of the knee-joints. I learned that he had been treated with mercury, but had borne it badly. In September he had inflammation of the left ankle-joint, and complained of cough, with weakness, night sweats, and great dyspnoea. In spite of the best care, he became rapidly worse, and in November there was evidence of diffuse infiltration in both lungs. He continued to fail very fast, and died early in December.

From a study of these and other cases Dr. Taylor said that he had arrived at the following conclusions:

*First*, that syphilis predisposes to tuberculosis, and

*Second*, that there are certain clinical manifestations which depend on the morbid changes that are produced in the lungs by syphilis.

DR. SATTERTHWAITE then read a letter on the subject of pulmonary tuberculosis, which he had received from Prof. Wm. H. Welch, of the Johns Hopkins University of Baltimore, in which he spoke of the state of confusion in which the matter of syphilitic lesions in the lung still continued, and expressed the opinion that it was not very likely to be cleared up before we possessed, by the detection of the specific germ of syphilis, as positive a means of recognition of syphilitic lesions as we had in the tubercle bacillus for tuberculosis. Unquestionably a large proportion of the cases of pulmonary syphilis reported in the adult had been cases of tuberculosis. Some writers seemed to suppose that by demonstrating the existence of syphilis in the patient, they had brought sufficient evidence that the coincident pulmonary disease was of a syphilitic nature. Neither the existence of syphilitic infection, nor improvement or cure of the pulmonary affection by antisyphilitic treatment, seemed to him satisfactory proof that the alteration in the lung was syphilitic. In the present unsettled state of the question a case reported clinically, without any post-mortem examination, was valueless as to the establishment of specific pulmonary syphilitic lesion. It was curious to find that even in recent years cases had been reported as syphilis of the lung on the basis of the clinical history, even without examination of the sputum for tubercle bacilli, as well as on the basis of post-

mortem examination without search for the tubercle bacilli.

The specific alterations in the lungs in cases of congenital syphilis, chiefly of still-born infants, had long been recognized, and their characters were understood. As regards acquired syphilis, there were two forms of pulmonary disease which he had met with, and which he thought were syphilitic. One was a form of chronic interstitial pneumonia, beginning usually at the root of the lung and extending along the bronchi and blood-vessels; and the second was the formation of genuine gummata. As to the latter it had been shown that they might develop as circumscribed syphilitic pneumonias. Although the lesions mentioned were, of course, accompanied with destruction of the pulmonary parenchyma, he knew nothing of the occurrence, from genuine syphilitic lesions, of such destruction of tissue and formation of cavities as we were accustomed to call phthisis; such cavities as were found in cases of the kind referred to being always small. In this sense there did not seem to him to have been as yet brought forward sufficient evidence to form the existence of such a disease as syphilitic phthisis.

DR. L. WEBER said that he found himself in accord with Drs. Satterthwaite and Taylor on this subject. In many cases he had undoubtedly a mixed affection; and it stood to reason that a chronic disease, like syphilis, in the course of its long history, would often become associated with other diseases. In many patients who had died of phthisis, he had found at the autopsy evidences of syphilis in the other organs. After the publication of Fournier's views, however, the tendency had no doubt been to attribute entirely too many cases of pulmonary disease to syphilis.

He desired on this occasion especially to call attention to two very interesting cases of syphilitic disease of the bronchi which it had been his privilege to have under observation. One of the patients died, but the other had recovered. The first was a gentleman thirty-three years of age who suffered greatly from dyspnoea, and had a syphilitic history. A careful examination of the fauces, larynx and trachea (as far as possible) revealed considerable disease of the bronchial mucous membrane, with thickening, but not ulceration. The treatment, which was partly a mixed one and partly one of plain iodide of potassium, had a remarkable effect in overcoming the attacks of dyspnoea. The patient afterwards died of some intercurrent affection, but whether this was of syphilitic origin he had not been able to ascertain. In this case there was no doubt a fibroid contraction of the trachea and bronchial tubes as a result of syphilis.

The second case was that of a woman twenty-two years old, a prostitute, who had become infected with syphilis at least six or seven years before, and had the characteristic syphilitic perforation of the soft palate. The symptoms, though not so severe, were very similar to those observed in the other case, and as in that instance yielded very satisfactorily to antisyphilitic treatment. He had now lost sight of the patient, though he had no doubt that she was still alive.

DR. W. H. PORTER said that he had tried very hard to secure some positive evidence of the engrafting of tuberculosis on syphilis, but he had not yet succeeded in accomplishing it. He could not see any reason, however, why this should not take place.

Post-mortem, the diagnosis of syphilis in any case was to be based principally on certain changes in the blood-vessels and the absence of tubercle bacilli.

DR. TAYLOR said that there was one point which he had neglected to refer to directly, although it could be incidentally inferred from some of the cases which he had related. In pulmonary syphilis the correctness of the diagnosis could often be established by the results of the treatment. We not infrequently heard of patients being cured of asthma by iodide of potassium; and when this was the case, he had no doubt whatever that the asthmatic trouble was of syphilitic origin.

In closing the discussion, DR. SATTERTHWAITE said that he had expected that an earnest advocate of the other side of the question would be present on this occasion to dispute the conclusions which he had given in his paper, but the gentleman had not appeared. It seemed to him that sufficient evidence had been produced to show that there was unquestionably such an affection as pulmonary syphilis; and this evidence was cumulative. In regard to the pathological changes, we not infrequently found miliary gummy deposits in the lung associated with the characteristic syphilitic cirrhosis of the liver. Such cirrhosis of the liver was peculiar, and very different from alcoholic cirrhosis. Then we had periostitis, and, finally, the clinical history. One peculiar feature was the albuminuria, which was much more common than in tuberculosis. In addition, we had all these signs without any history of tuberculosis.

He then spoke of the peculiar hyaline degeneration of the vessels met with in pulmonary syphilis, and referred again to the case of Dr. Zeh, mentioned in the paper, in which an autopsy was made, where the lesions closely resembled those of tuberculosis, but which was, undoubtedly, purely syphilitic. Specimens of the lung tissue were sent to every laboratory in the city, and the reply was made in every instance that absolutely no tubercle bacilli could be found; although some of the microscopists expressed their conviction that the case, nevertheless, was one of tubercular phthisis.

In reference to Professor Welch's views, he agreed with him that in pure syphilis of the lung the cavities were always small. He regretted that he had had only six cases of his own confirmed by autopsy, but in those the evidence was entirely conclusive.

In regard to Dr. Porter's statement that tuberculosis was not apt to be engrafted on syphilis, he said that he had some cases where syphilis was undoubtedly engrafted on tuberculosis. His experience went to show that in about 50 per cent. of all cases tuberculosis is found, together with syphilis. On the whole, however, it must be admitted, as shown by his statistics, that syphilis of the lung was comparatively rare.

He was quite willing to admit that there were two views of this question, and that there were good authorities on both sides of it. In his paper he had endeavored to do justice to both. While pulmonary syphilis was comparatively rare, he was convinced that some of the cases entirely escaped notice, being mistaken for bronchitis, broncho-pneumonia, or ordinary tuberculosis. One of the peculiarities of such disease was that while the physical signs were often well marked, the constitutional symptoms were exceedingly slight; there being but little increase of temperature, and the patient's appetite and general

strength remaining fairly good as well. This was an important point in the diagnosis; as was also the fact of relief secured by the administration of anti-syphilitic remedies.

DR. H. N. HEINEMANN then read a paper on  
PROGNOSIS IN VARIOUS FORMS OF ORGANIC DISEASE  
OF THE HEART.

## MEDICAL AND SURGICAL SOCIETY OF BALTIMORE.

J. WILLIAM FUSCK, M.D., SECRETARY.

STATED MEETING HELD THURSDAY, APRIL 23, 1891.

THE 725th meeting of the Society was called to order by the President, DR. DAVID STREETT. Minutes of previous meeting read and approved.

DR. WILMER BRINTON, exhibited a patient with

### PURPURA HÆMORRHAGICA RHEUMATICA.

Male, age twenty-six, came under care about ten weeks ago for an attack of rheumatism. Family history good, except that his father died of epithelioma of the lip. In the course of the last ten weeks his entire body has been covered with hæmorrhagic spots. The throat and conjunctiva are involved, but no other mucous membrane, except, perhaps the genito-urinary tract, but as he has taken turpentine to the point of strangury, the blood in the urine may be due to that cause and not to any purpuric manifestation in the genito-urinary tract. His gums have been firm and appetite good throughout the attack, which has been in his favor. He has taken, during the last ten weeks, gallic acid, iron, ergot, turpentine, etc., and at times he would seem to improve, but in a day or two his body would become covered over again with a fresh crop of purpuric spots. The spots are smaller at this time than they have been heretofore. He had a patch on the right side, some days ago that was about 5 x 10 inches in size, where a mustard plaster had been. In answer to inquiries, he said that the patient had not taken any antipyrine to his knowledge.

DR. D. W. CATHELL said he had been fortunate in not being called upon to treat many such cases, he had seen eight or ten, but this case does not resemble any that he had ever seen. This is evidently due to a depraved condition of the blood, the spots in this case are so well defined and discreet, they do not coalesce and do not show the lemon color on fading. In the other cases he had seen, the hæmorrhagic areas were large blotches, some of which would measure 7x10 in. As to treatment, he had found Blancard's iodide of iron pills to be beneficial in some of his cases.

DR. F. C. BRESSLER, said he had seen three or four cases, the first of which was an Italian, in whose case the purpuric spots were very marked about the joints, the case responded very slowly to treatment and finally passed out of his hands. About six weeks ago a young man came to his office, whose nose had been bleeding for some time. He had to plug the nostrils finally to control it, and gave some fluid extract of hamamelis. Next day he had some hæmorrhagic spots on the mucous membrane of the lips, but the extravasations were not extensive, he recovered under aromatic sulphuric acid. The reason he had asked if antipyrine had been administered was, that we know that drugs sometimes cause these extravasations, and he thought it might

possibly be traced to some such cause. It was thought that purpura was a disease of the blood, but this view has been abandoned now, it is one of two things, either some toxic material circulating in the blood or a disease of the vessel walls, allowing of the extravasation of the blood through them into the adjacent tissues.

DR. D. W. CATHELL exhibited a case of

#### ALOPECIA UNIVERSALIS.

A mau, age thirty-nine, family history good, there has not as yet been a death in the immediate family. The patient had never had occasion for the services of a doctor at any time in his life until he had *la grippe* in February, 1890. The attack was of nine days duration and he was treated by a druggist. During the next month (March) he noticed little patches of baldness here and there and in May it extended from his head to his whiskers. He shaved for the last time on the 6th of October, 1890. At present (April 23, 1891), there is not a hair on his body. From being a man with an abundance of hair (as shown by his picture), and so heavy a growth of whiskers, that barbers did not care to have him as a customer, he is now entirely and universally bald. He is in perfect health now, except a little dysuria. There are parasitic diseases which might destroy the hair but these diseases are infectious, and as the patient has a family, they would be most likely to become infected, but as they show no infection whatever, we may disregard that source as the cause of the present condition. He was inclined to the belief that it was due to some glandular disturbance, possibly an interference with the nutrition of the hair follicles.

DR. F. C. BRESSLER said these cases are very rare and the etiology is obscure, there are two theories in regard to it, one that it is neurotic and the other that it is due to bacteria; the neurotic theory seems to be received with more favor of the two. Prentiss, of Washington, has reported that jaborandi has a stimulating effect on the growth of hair, in that it restores gray hair to its natural color. It is questionable whether jaborandi would be beneficial in this case, but it might be worth a trial.

DR. THOMAS A. ASHBY exhibited a specimen of

#### RUPTURED TUBAL PREGNANCY.

A colored woman was suddenly seized with pain and collapse; her physician was called in and diagnosed a ruptured tubal pregnancy. Dr. Ashby was sent for and agreed in that diagnosis, but her surroundings were such that he thought it inexpedient to operate unless she could be removed. In two or three days she had another attack and she was brought into the Maryland General Hospital. She developed a peritonitis and on April 24, he did a laparotomy. The pelvis was full of bloody serum and blood clots, the ruptured tube was excised and about half of the omentum had to be removed on account of its gangrenous appearance. She is doing fairly well, though she is not yet out of danger. She may perish from peritonitis or from septic trouble. The fetus in this case was not recognized, as is often the case in early ruptures: This occurred in the eighth or ninth week of gestation. The development of the fetus after rupture is dependent on the site of the rupture. If the rupture takes place into the peritoneum, the fetus is apt to perish, if it takes place in the broad ligament it may go on to further development. Rupture generally occurs early,

between the fifth and twelfth week, if it goes on beyond the twelfth or thirteenth week, it may go on to maturity. In answer to the question "how long would you wait before operating?" he said it would depend on the surroundings of the patient. If the surroundings were such that sepsis could be attained, it would be advisable to operate immediately, if the surroundings were unfavorable, an effort should be made to tide her over until she could be moved to where the conditions would be more favorable. If the rupture occurs in the peritoneum she may bleed to death in a short time, if it occurs in the broad ligament she has a better chance.

DR. WILMER BRINTON said in the last ten years there has been a decided advance in our knowledge on this subject. Electricity is being abandoned and it is being generally accepted that laparotomy is the best treatment. But every doctor cannot do a laparotomy, and electricity in the hands of the average man will continue to be used. It is important that a diagnosis should be made in these cases. He knew of a case where the physician was called and saw the case within an hour of the attack, the doctor took it to be a case of colic, and gave her morphia and left some for her to take. He was sent for again and saw her within seven hours from the attack and she died while he was there.

DR. F. C. BRESSLER said this condition cannot be recognized before rupture takes place, this is accepted, so the general practitioner should bear in mind the possibility of an ectopic gestation when he is consulted by a woman for irregular menstruation, and where there are any of the earlier signs of pregnancy.

### Recent Literature.

*Twelve Lectures on the Structure of the Central Nervous System.* By LUDWIG EDINGER, M.D. Translated by WILLIS HALL VITHEM, M.D. Edited by C. EUGENE RIGGS, A.M., M.D. 8vo, pp. xii, 230. With 133 illustrations. Philadelphia and London: F. A. Davis. 1890.

Edinger's lectures are familiar to every neurologist as the clearest introduction to the study of the anatomy of the central nervous system that has yet appeared. It is therefore with pleasure that we greet this attempt to make the work accessible to the student who does not know German. The work of translation has been well done, and we are spared the Germanized language which is employed by so many translators in place of English. The profession should be grateful to Dr. Vitheim for having done his task so well. The work itself needs no commendation. It is indispensable to every physician who wishes to learn something of the anatomy of the brain and cord. The excellent illustrations of the original have all been reproduced, but although still intelligible, they have lost much of their beauty and clearness in the process of reproduction.

THE MEDICAL AND SURGICAL REPORTER.—DR. E. T. REICHERT has taken editorial charge of the *Philadelphia Medical and Surgical Reporter*, taking the place of Dr. C. W. Dufles, who resigned a few weeks ago.

THE BOSTON  
Medical and Surgical Journal.

THURSDAY, JUNE 11, 1891.

*A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.*

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DANRELL & UPHAM,  
283 WASHINGTON STREET, BOSTON, MASS.

THE BOSTON LYING-IN HOSPITAL.

The great changes which have been effected in the equipment and management of the Boston Lying-in Hospital during the past year have induced the trustees to publish an extended account of its past history and present condition, in connection with their fifty-eighth annual report, for 1890.

The hospital was incorporated in 1832, and was at first situated on Washington Street, near the present location of Waltham Street. In 1853 it was removed to a larger building on Springfield Street, but at the end of a year was obliged to discontinue its work, for the time, on account of an insufficient pecuniary support.

Its funds were, however, wisely managed; and at the end of about twenty years it was enabled to take a fresh and vigorous start. It was reopened in its present situation on McLean Street on January 1, 1873; and from that time to this its history has been that of a constantly increasing prosperity and usefulness.

In 1873, the work was carried on in a single small dwelling-house, which was but slightly altered from its original design, and contained but eighteen beds. One hundred and sixty patients were received and treated during the year. In 1877 the work had increased so much that it was necessary to enlarge the building by the purchase of the adjoining house. In 1887 the growing usefulness of the hospital compelled the purchase of two more houses, but it soon became evident that so large a clinic could not any longer be properly or economically administered in so inconvenient and cramped a building.

The capacity of the hospital was insufficient to meet even the existing wants, and the demands upon it were constantly increasing. Larger accommodations for patients, nurses, employees, and house-officers had become necessary, unless the work of the institution was to be curtailed.

The trustees, believing that the time had come to meet these demands, and regarding the present loca-

tion of the hospital as an excellent one for the institution, had plans made for the alteration of the four houses on McLean Street, constituting the present block belonging to the corporation, which would combine them into one hospital building, with wards, and reception, isolating, and operating rooms, all admirably adapted to the improved methods of the present day, and sufficient to meet its anticipated needs for many years to come. The plans included the erection upon the rear of the land of adequate buildings, in connection with the hospital, for the kitchens, laundry and servants' quarters. An adjoining property was purchased at the same time, which with slight changes will be directly connected with the main hospital, and will supply the necessary requirements of a house for general administrative and out-patient purposes.

The work of improvement and extension has been begun, and will, it is expected, be completed in October or November of the present year, when the corporation will have the largest and best equipped hospital of the kind in this country.

In order to defray the expenses of the rebuilding and improvements, a fund of one hundred thousand dollars was sought. In the space of a few months the friends of the institution quietly contributed this generous sum, and at the present date welcome and necessary additions are still making to the amount. Annual subscriptions to meet the increased running expenses are also desired.

Early in the year 1890, the trustees further decided to make a radical change in the medical care of the hospital, and to adopt the principle of continuous service. With this end in view, it was decided to place the hospital in the charge of one visiting physician to be assisted by an assistant visiting physician and by three physicians to out-patients.

The adoption of this plan has been followed by an increased efficiency in the medical management of the hospital, and the arrangement has proved highly satisfactory, both to the trustees and to the medical staff.

The training-school connected with the hospital has also witnessed changes looking to an improvement in the character of the instruction given. Instead of one course of lectures given during the winter season, two courses of twenty lectures each were given by the members of the medical staff. One of these was in the summer and autumn, the other in the winter and spring. By this arrangement, the whole subject of obstetric nursing is taught twice a year, thus providing that all the nurses shall be able to attend at least one full course of lectures.

The time required for obtaining the diploma has been changed to six months for graduates of recognized training-schools and fifteen months for non-graduates. The office of director of nurses was also created.

The annual report of the visiting physician for 1890 is of especial interest from a more strictly medical point of view. The statistics which it details certainly

furnish convincing evidence of the advances which have been made in midwifery in recent years.

During the year, one thousand and thirty-nine (1,039) women were delivered under the care of the hospital, five hundred and nine (509) of whom were attended in the wards, and five hundred and thirty (530) at their homes, as out-patients. In spite of the many desperate cases which are sent to the hospital, and the squalid and neglected class of women who are treated as out-patients, but one of the mothers was lost, and that a woman who entered moribund after many eclamptic seizures, and died within a few hours, the baby being saved. This record is certainly one extremely creditable to those in charge.

### PULMONARY SYPHILIS IN THE ADULT.

In another part of this issue will be found an interesting paper, embodying much laborious research, upon the above subject, and also the discussion to which it gave rise at a meeting of the New York Academy of Medicine. The occurrence of pulmonary syphilis, pure and simple, apart from tuberculosis, has before now been positively affirmed and as positively denied. Dr. Satterthwaite has endeavored to throw light upon the disputed question by investigations at the bedside and at the autopsy table, undertaken by himself and others. He submits six cases of his own, confirmed by autopsy, in which he considers the evidence was entirely conclusive; and refers to a seventh case, in which an autopsy was made, where the lesions closely resembled those of tuberculosis, but no tubercle bacilli were found, though specimens of the lung were submitted to careful examination in several laboratories.

Dr. R. W. Taylor reports four cases in which the diagnosis was made clinically; in three the pulmonary signs disappeared under syrup of iodide of iron and a mixed specific treatment.

Dr. L. Weber reports two cases of syphilitic disease of the bronchi.

Dr. Satterthwaite expresses the opinion that sufficient evidence exists to show that there unquestionably is such an affection as pulmonary syphilis; and this evidence is cumulative. In regard to the pathological changes, we not infrequently find milary gummy deposits in the lung associated with the characteristic syphilitic cirrhosis of the liver. Such cirrhosis of the liver is peculiar, and very different from alcoholic cirrhosis. Then we have periostitis, and finally the clinical history. One peculiar feature is the albuminuria, which is much more common than in tuberculosis. In addition, we have all these signs without any history of tuberculosis. In pure syphilis of the lung the cavities are always small. While agreeing that pulmonary syphilis is comparatively rare, he is convinced that some of the cases entirely escape notice, being mistaken for bronchitis, broncho-pneumonia, or ordinary tuberculosis. One of the peculiarities of such

disease is that, while the physical signs were often well marked, the constitutional symptoms are exceedingly slight, there being but little increase of temperature, and the patient's appetite and general strength remaining fairly good as well. This is an important point in the diagnosis; as is also the fact of relief secured by the administration of anti-syphilitic remedies.

Dr. Wm. H. Welch, of the Johns Hopkins University, contributed a letter in which he expressed the opinion that the existing confusion in regard to syphilitic lesions of the lung was not very likely to be cleared up before we possessed, by the detection of the specific germ of syphilis, as positive a means of recognition of syphilitic lesions as we have in the tubercle bacillus for tuberculosis. Unquestionably a large proportion of the cases of pulmonary syphilis reported in the adult have been cases of tuberculosis. Neither the existence of syphilitic infection, nor improvement or cure of the pulmonary affection by anti-syphilitic treatment, seemed to him satisfactory proof that the alteration in the lung was syphilitic. In the present unsettled state of the question, a case reported clinically, without any post-mortem examination, is valueless as to the establishment of specific pulmonary syphilitic lesion. It is curious to find that even in recent years cases had been reported as syphilis of the lung on the basis of the clinical history, even without examination of the sputum for tubercle bacilli, as well as on the basis of post-mortem examination without search for the tubercle bacilli.

As regards acquired syphilis, there were two forms of pulmonary disease which he had met with, and which he thought were syphilitic. One was a form of chronic interstitial pneumonia, beginning usually at the root of the lung and extending along the bronchi and blood-vessels; and the second was the formation of genuine gummata. As to the latter it had been shown that they might develop as circumscribed syphilitic pneumonias. Although the lesions mentioned were, of course, accompanied with destruction of the pulmonary parenchyma, he knew nothing of the occurrence, from genuine syphilitic lesions, of such destruction of tissue and formation of cavities as we were accustomed to call phthisis; such cavities as were found in cases of the kind referred to being always small. In this sense there did not seem to him to have been as yet brought forward sufficient evidence upon which to base the existence of such a disease as syphilitic phthisis.

Whilst many practitioners will affirm that their experience has convinced them of the occurrence of a pulmonary syphilis, the acquisition of positive proof in support of this conviction is attended with many difficulties; and the negative side of the question, though by no means necessarily the correct one, will probably continue to be the easier one to maintain until, as suggested by Dr. Welch, we have eliminated a specific organism occupying the same diagnostic relation to syphilis that the tubercle bacillus is generally accepted as occupying toward tuberculosis.

## MEDICAL NOTES.

JEFFERSON MEDICAL COLLEGE.—The Trustees of the College have unanimously elected Dr. J. M. Da Costa, Emeritus Professor of Clinical Medicine, and Dr. Roberts Bartholow, Emeritus Professor of Materia Medica and Therapeutics.

UNIVERSITY OF PENNSYLVANIA.—The Trustees of the University of Pennsylvania have elected Dr. George A. Peirsol, Professor of Anatomy; Dr. Harrison Allen, Professor of Comparative Anatomy; Dr. John B. Deaver, Assistant Professor of Applied Anatomy; and Dr. Edward Martin, Clinical Professor of Genito-Urinary Surgery.

THE DIRECTIONS FOR THE USE OF TUBERCULIN which are given out with the fluid have been changed in that part relating to a repetition of the dose after a rise of temperature, so that they now read as follows: "Should the temperature rise above 38° C. (100.4 F.), in consequence of an injection, the following dose should not be increased. The same, or a smaller dose is then so long employed, until the temperature remains below 38° for several days at a time. In any event, the injections must not be continued before the phenomena of the reaction have subsided."

FUMIGATION OF PARLIAMENT.—In the British House of Commons, "in reply to questions by Mr. Caldwell and Mr. Vincent, Mr. Plunket, the First Commissioner of Works, stated that he was well aware of the ravages which the prevailing epidemic of influenza had made amongst the members of this House, and he had given directions that the committee rooms should forthwith be fumigated with sulphur. He would adopt at once the same process in such other parts of the House as it may seem possible, and would avail himself of the recess for completing the operation."

ADVICE FROM JAPAN.—The following clipping from a Japanese exchange shows that with the adoption of Western medical methods in the empire, the pitfalls of medical practice have not been entirely avoided: "A woman, named Kin Mihashi, at 20, having been suffered from the uterine disease, consulted of a physician at *Yokohama*, who administered anæsthetic. While under the influence of the drug, as she stated that the Doctor conducted the immoral action, and appeared before the court yesterday. It is advisable for a young physician not to give anæsthetic without the presence of another professional man, especially in case of female, as the effect of the drug often gives such a peculiar strained sensation to the patient as some one insulted her immorally while under the influence of the drug."

## BOSTON AND NEW ENGLAND.

BOSTON NORMAL SCHOOL OF GYMNASTICS.—At the graduating exercises of this school last week, thirty-two young women received degrees. The certificates were presented by Larkin Duntton, Esq., and addresses were delivered by Dr. G. Stanley Hall, Dr. Walter Channing and Rev. A. C. A. Hall.

RESIGNATIONS.—Dr. G. G. Tarbell has resigned from the medical staff of the Massachusetts General Hospital. Dr. A. R. Moulton has submitted his resignation as Inspector of Institutions, Massachusetts State Board of Lunacy and Charity, and after a trip abroad will join the staff of the Pennsylvania Hospital.

HARVARD MEDICAL SCHOOL ASSOCIATION.—The first annual dinner of the Harvard Medical School Association, will be held at the Hotel Vendome, at 1 o'clock, on Tuesday, June 23d, the day before Commencement. The annual business meeting will be held at the Harvard Medical School, Boylston Street, at 12 o'clock, before the dinner. There will be an opportunity to visit the laboratories, etc., of the Medical School.

ANNUAL MEETING OF MASSACHUSETTS MEDICO-LEGAL SOCIETY.—The annual meeting of this Society was held at the rooms of the Medical Library Association, at 12 o'clock on Tuesday, June 9th. The following were elected as officers for the year: President, Dr. F. W. Draper, Boston; Vice-President, Dr. Z. B. Adams, Framingham; Treasurer, Dr. C. C. Tower, Weymouth; Corresponding Secretary, Dr. B. H. Hartwell, Ayer; Recording Secretary, Dr. Thos. M. Durell, Somerville.

A PROTEST AGAINST AN AID ASSOCIATION.—A largely attended meeting of the Hampden District Medical Society was held on Monday to take action upon objections raised by the local physicians to the methods of the Medical Aid and Sanitary Association. It was voted that the methods of the association are in direct contravention of the ethics of the medical fraternity. The Medical Aid and Sanitary Association was organized recently to secure for families medical attendance on a co-operative plan, each subscriber being entitled to all necessary medical attendance without further charge. Three physicians had lent their names to the association, but withdrew them when objections were brought forward by other medical men.

OFFICERS OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.—The following officers were elected at the annual meeting April 25, 1891: President, Edward N. Whittier; Vice-President, A. L. Mason; Secretary, James J. Minot; Treasurer, Edward M. Buckingham; Librarian, B. J. Jeffries; Commissioner of Trials, C. W. Swan; Member of the Nominating Committee of the Massachusetts Medical Society, W. L. Richardson; Committee of Supervision, F. Minot, W. Ingalls; Committee on Social Meetings, Harold Williams, G. A. Leland, R. W. Lovett, Edward Reynolds; Censors, H. L. Burrell, G. M. Garland, F. H. Davenport, H. F. Vickery, F. B. Harrington; Councillors, S. L. Abbot, J. B. Ayer, H. J. Barnes, C. J. Blake, A. N. Blodgett, H. I. Bowditch, E. H. Brigham, F. E. Bundy, J. F. S. Bush, A. T. Cabot, J. R. Chadwick, D. W. Cheever, J. W. Cushing, E. G. Cutler, B. F. Campbell, F. W. Draper, T. W. Fisher, R. H. Fitz, C. F. Folsom, M. F. Gavin, C.

M. Green, J. O. Green, F. B. Greenough, W. H. H. Hastings, W. C. Holyoke, J. Homans, W. Ingalls, B. J. Jeffries, C. M. Jones, F. I. Knight, A. L. Mason, A. E. McDonald, J. H. McCollom, F. Minot, A. B. Morong, C. B. Porter, A. Post, C. P. Putnam, W. L. Richardson, T. M. Rotch, G. B. Shattuck, G. C. Shattuck, B. S. Shaw, A. D. Sinclair, A. M. Sumner, C. W. Swan, G. G. Tarbell, O. F. Wadsworth, J. C. Warren, A. P. Weeks, J. C. White, E. N. Whittier, E. Wigglesworth, H. W. Williams.

#### NEW YORK.

**A TRIBUTE TO THE MEMORY OF DR. FORDYCE BARKER.**—At the last meeting of the New York Academy of Medicine for the present season, held June 4th, the President, Dr. Alfred L. Loomis, paid a tribute to the memory of Dr. Fordyce Barker, Ex-President of the Academy. Dr. Barker's portrait was draped with black.

**FUNERAL OF DR. BARKER.**—The funeral of Dr. Fordyce Barker at St. Thomas's Church on June 2d, was very impressive. The large church was completely filled, and the services were conducted by Bishop Potter, the Rev. Dr. Morgan Dix, of Trinity, the Rev. Dr. John W. Brown and the Rev. Henry M. Kirkby, of St. Thomas's and the Rev. Dr. Henry G. Satterlee, of Calvary, assisted by the quartette choir of St. Thomas's. Among the pall-bearers, none of whom were medical men, were Clarence A. Seward, Gen. George W. Cullum, and Judge Abraham R. Lawrence. The Fellows of the New York Academy of Medicine attended in a body, and besides the faculties of the medical schools of New York and Brooklyn and the students of Bellevue, there were present representatives of the State and County medical societies and a general gathering of the profession, as well as a large assemblage of other friends.

**APPOINTMENTS AT COLUMBIA COLLEGE.**—At a meeting of the Trustees of Columbia College, held June 1st, Prof. E. B. Wilson, of Yale, and Dr. Bashford Dean were appointed respectively Adjunct Professor and Instructor in Biology, and were granted a year's leave of absence to enable them to pursue a course of study in Germany previous to the opening of the Department of Biology in October, 1892.

**CHANGES AT THE UNIVERSITY OF THE CITY OF NEW YORK.**—At a meeting of the Council of the University of the City of New York, held the same day, the resignation of the Rev. Dr. John Hall, as Chancellor of the University, was received. Dr. Henry P. Loomis was elected Professor of Pathological Anatomy in the medical department.

**AN EYELSS INFANT.**—A young infant was recently brought to the New York Eye and Ear Infirmary which was said to have been born without eyes. On making an examination, Dr. John E. Weeks found that there was a rudimentary eye on the right side, but no trace of one on the left side. The parents were represented as being in good health.

## Miscellany.

### THE ARROW POISON OF THE PIGMIES.

**SURGEON PARKE**, the medical officer of Stanley's expedition, has recently given a lecture before the London Pharmaceutical Society, on the arrow poisons of the pigmy race. The poisons are evidently of a very fatal character, since all members of the expedition, with one exception, who were struck by the arrows, died. The poison is made by pounding together into a paste the bark of a certain tree, some long, green leaves from a herbaceous plant, the shoots of a creeper, scrapings from the stem of a common shrub, and a few small seeds. The whole is made into a paste which is stuck on the tops of the arrows, and allowed to dry. It is said to lose its strength in a few days.

From specimens brought home, some of the plants have been identified. It is probable that the mixture owes its poisonous qualities largely to strychnine and erythrophloin.

### DANGERS OF SULPHONAL.

ALTHOUGH sulphonal is probably one of the safest, as it is one of the most efficacious, among the hypnotics recently introduced, the series of cases published by Bresslau, of Vienna, show clearly that it has certain dangers.<sup>1</sup> The degree of peril is difficult to estimate, as the patients were lunatics, and were also apparently feeble; but the fact is significant that out of seventy-seven patients who were treated with the drug, no less than seven showed serious symptoms, and in five of these there was a fatal termination. It ought to be mentioned that the patients had been taking the drug for a considerable time in good doses, and had borne it well until symptoms of disturbance set in, these being great constipation, dark-brown urine, slow, or in some cases rapid but feeble pulse, discolored patches resembling purpura on the limbs, and great prostration. In the cases which ended fatally, the cause of death was heart-failure, with œdema of the lungs.

### VITAL PHENOMENA AFTER DECAPITATION.

**LABORDE** noticed the following phenomena in the head and body of the notorious Eyraud immediately after decapitation by the guillotine.<sup>2</sup>

Immediately after the execution there was noted marked corrugation of the forehead extending to the vertex; associated ocular movements; opening and slanting movement of the mouth of a respiratory type. The palpebral reflex could be plainly evoked for from fifteen to twenty minutes after decapitation, during which time the iris remained sensible to the stimulus of light. Simultaneously with the placing of the trunk in the basket there were noticed up and down movements of the arms, plainly visible despite the fact that they were firmly ligatured to the sides. This phenomena is, it appears, well known to Diebler's assistants, who, in their figurative language denominate it "the flapping of the wings." The feet were strongly re-

<sup>1</sup> *Lancet*, April 1, 1891.

<sup>2</sup> Correspondence of the *Journal American Medical Association*.

tracted, and when M. Laborde pinched the arm, the trunk being in the basket, a reflex movement was very apparent. As M. Laborde remarks, these reflex movements are strictly analogous to those perceived in the abattoirs, where the stimulation of a member immediately after falling produces a violent kick.

### MICROCIDINE.

BERLIOZ<sup>1</sup> describes a new antiseptic under this name. It is composed of seventy-five per cent. of naphtholate of sodium and twenty-five per cent. of naphthol and phenyl compounds. It is a white powder obtained by adding to fused B-naphthol half its weight of caustic soda, and allowing the mixture to cool. It is soluble in three parts of water, and the solution, which is cheap, is said to possess considerable antiseptic powers, without being toxic or caustic, or injurious to instruments or linen. Its antiseptic properties, while inferior to those of corrosive sublimate or naphthol, surpass those of carbolic and boric acids ten and twenty times, respectively. It is eliminated by the kidneys, and is antipyretic. M. Polakillon has experimented with this new agent largely as a dressing to recent and other wounds, utilizing as a dressing, after a preliminary cleansing of the raw surface with a three-per-cent. solution, gauze soaked in the same and covered with a layer of oil-silk and a thick pad of cotton-wool. The results are reported to have been excellent.

### AN UNTREATED AMPUTATION BY A LOCOMOTIVE.

DR. D. HAYES AGNEW<sup>2</sup> reports the following case, described by Dr. W. W. Stennett:

A switchman in a retired part of one of the yards of the Chicago and Northwestern Railroad picked up the arm of a man which had been crushed off at the shoulder-joint and having on it a shirt sleeve. Diligent search was made for the owner of the lost member, but nowhere could he be found, nor could any clue to the accident be discovered. Five days after the accident the police found the man at Clyborn, five miles from the scene of the injury, exhibiting his mutilated shoulder in proof of his arm having been cut off by a train. This exhibition he had made in twenty or thirty saloons for the purpose of obtaining whiskey. During all the time no dressing had been applied, or any vessels tied. He was sent to a hospital and recovered perfectly. On examination it was found that the arm had been torn out of its socket, leaving the other elements of the shoulder, the clavicle and scapula, intact.

Dr. Agnew remarks that the forcible ablation of an arm has often occurred by machinery without any serious loss of blood, but the shock usually renders the patient helpless, and the surgeon invariably feels it his duty to ligate the crushed vessels. The marvel, however, in this case, was the ability of the man to travel about for five days, realizing neither shock nor bleeding. It is not improbable that had one or two days more elapsed without a dressing, fatal bleeding would have ensued from sloughing of the crushed vessels, such sloughing often being delayed as late as the seventh day.

### IDENTITY OF SMALL-POX AND COW-POX.

ETERNOD and HAXIERS,<sup>1</sup> from the results of their experiments on the transference of small-pox from man to the calf, are convinced that small-pox and cow-pox are caused by the same virus. For the purpose of inoculation small-pox lymph from cases varying in severity was used, and was rubbed into a moderately large extent of scarified skin in the abdominal region of the calf. The first inoculation was followed in every case by a scanty crop of pustules at the spot chosen. This eruption had at first very little resemblance to typical cow-pox, but on transferring the disease from calf to calf it became more and more characteristic, until, in the opinion of the authors, it was impossible to distinguish it from true cow-pox. The calves vaccinated in this way with human small-pox lymph were found in every case to be refractory to vaccination with ordinary cow-pox lymph.

### OPERATION FOR OPENING THE POSTERIOR MEDIASTINUM.

In a recent communication to the Société de Chirurgie of Paris, M. Quenu described an operation he has lately devised, in association with M. Hartmann, for gaining access to the posterior mediastinum.<sup>2</sup> A vertical skin incision is made midway between the spinal border of the scapula and the vertebral column. After division of the exposed portions of the trapezius and rhomboid muscles, and displacement inwards of the outer border of the sacro-lumbalis, a portion of the entire thickness of each bone and about three-quarters of an inch in length is taken from the third and each of the two following ribs. An opening is thus formed nearly five inches in length, and extending from the first rib to the upper border of the sixth. Quenu states that by separating the sides of this wound one can see very clearly the whole of the posterior mediastinum and all the organs it contains. This operation, it is pointed out, is attended with more difficulty and danger on the right than on the left side, because, as was first shown by Braune, the pleura, which on the left side passes directly from behind forwards, insinuates itself on the right side between the œsophagus and the vertebral column in order to reach the aorta. Operative penetration into the posterior mediastinum might, it is thought, be indicated in disease of any organ contained in this part of the thoracic cavity, but is most likely to be needed in cases of impacted foreign body in the lower part of the œsophagus. The anatomical conditions in this operation are not favorable to removal of malignant disease of the gullet unless the growth is of very limited extent.

### CORROSIVE SUBLIMATE AS A DISINFECTANT.

DR. A. C. ABBOT<sup>3</sup> has published the results of his careful and thorough investigation of the destructive power of solutions of corrosive sublimate upon the most common of the micro-organisms of suppuration, the staphylococcus pyogenes aureus. From these investigations the author comes to the following conclusions:

<sup>1</sup> Académie de Médecine, April 28th.

<sup>2</sup> University Medical Magazine, June, 1891.

<sup>1</sup> Semaine Médicale, No. 65, 1890.

<sup>2</sup> British Medical Journal, from Revue de Chirurgie, No 3, 1891.

<sup>3</sup> Johns Hopkins Hospital Bulletin, April, 1891.

Under the most favorable conditions a given amount of sublimate has the property of rendering inert only a certain number of individual organisms. That is to say, the process is a definite chemical one, taking place between the protoplasm of the individual bacteria and the sublimate in the solution. The disinfecting activity of the sublimate against organisms is profoundly influenced by the proportion of albuminous material contained in the medium in which the bacteria are present. The relation between the golden pyogenic staphylococci and sublimate is not a constant one, organisms from different sources and of different ages behaving differently when exposed to the same amount of the disinfectant, for the same length of time. The organisms which survive the exposure to the sublimate, may experience a temporary attenuation. This attenuation, however, may be caused to disappear by successive cultivation in normal media. By the method employed in these experiments it is possible to select from a culture the most resistant forms in that culture. Many of the results of previous experimenters, who have assigned to corrosive sublimate more powerful disinfectant properties against the staphylococcus pyogenes aureus in cultures than the observations reported in this paper indicate, are attributable to the neglect of certain precautions now recognized as essential to the proper conduct of such experiments.

In the light of these experiments and those of the experimenters quoted in the paper, it is plain that for use in surgical practice the solutions of corrosive sublimate do not possess all of the advantages hitherto attributed to them.

To the employment of sublimate solutions upon wound-surfaces, it is plain that there exist at least two serious objections. First, the albumen of the tissues and fluids of the body tends to diminish the strength of, or indeed renders entirely inert, the solution employed. And second, the integrity of the tissues is materially injured by the application of solutions of this salt.

The first objection cannot be met with certainty, for the surgeon possesses no means by which he can determine the amount of albuminous material with which his solutions are to come in contact, and in any case this large amount of albuminous material is an almost insuperable obstacle to complete disinfection with sublimate. He is, therefore, never in a position to say, *a priori*, that his efforts at disinfection of the wound are or are not successful.

The second objection is equally serious. During the past two years we have had sufficient evidence to lead us to believe that the normal tissues and fluids of the body possess the power of rendering inert many kinds of organisms which may have gained access to them. This function is therefore diminished, or, indeed, may be quite destroyed, by any agent which brings about alterations in the constitution of these tissues. We know that just such changes as those to which we refer are known to follow the application of sublimate solutions. It is plain then if we bring about in these tissues a condition of superficial necrosis, the condition following upon the application of sublimate, they are much less able to resist the inroads of infectious organisms than they would have been had they been left in their natural condition.

As a disinfectant, in the strict sense of the word, there are, perhaps, few substances which possess the

property in a higher degree than does corrosive sublimate, but at the same time there is nothing which is employed for this purpose that requires greater care in its manipulation in order to obtain its best results than does this salt. Its action is influenced by a number of conditions which in practical application it is difficult, if not quite impossible, to control.

For these reasons we seem hardly justified in continuing to give to it the first place in the list of substances which may be employed practically for the purpose of rendering harmless, materials containing the germs of infectious maladies.

## RESOLUTIONS OF THE OBSTETRICAL SOCIETY OF BOSTON ON THE DEATH OF DR. HOSMER.

A SPECIAL meeting was held June 5, 1891, to take action on the death of Dr. Hosmer, and it was voted that the following resolutions be entered in the records of the Society, that a copy be sent to the family of the deceased, and that they be published in the *Boston Medical and Surgical Journal*.

ALFRED HOSMER, M.D., M.M.S. Præses, A.A.S., a member since 1873, and a former president of this Society, died at his residence in Watertown, Mass., on the 14th of May, 1891, in the fifty-ninth year of his age.

Dr. Hosmer was highly esteemed by his associates. His contributions to the scientific work of the Society were always of a high order. His presence at our meetings was always welcome, and his communications and remarks were listened to with interest. He was an able, upright and energetic man, and one who inspired confidence in his fellow-men. As a natural consequence he was offered and held many honorable and responsible positions in and outside his profession. His long illness, which disabled him from professional and secular work, was a source of deep regret to his patients and associates. His illness and death have deprived this Society and the medical profession in Massachusetts of one of its most able, upright and energetic members.

(Signed) A. D. SINCLAIR,  
WM. L. RICHARDSON, } Committee.  
C. ELLERY STEEDMAN, }

Remarks were made by Drs. Brown, Ingalls, Minot, Blake and Cotting, on the character of Dr. Hosmer, and reminiscences were given of his life.

Dr. Cotting offered the following tribute to the memory of the deceased:

"As a member of this Society, our friend was always ardently devoted to its best interests and progress. His observations, for he was an acute observer of obscure points, previously unknown or unappreciated, impelled to further investigations and excited enthusiastic and most useful discussions. As President, he aggressively stimulated members to unwonted exertions regardless of any plea of inability or pre-occupation. In this and in all the responsible positions his over-active life inevitably placed him, he seemed urged on by innate inspiration as he allured to broader activities and led the way.

"His worth in the profession, his force in affairs, his unswerving integrity in all things were amply attested by the many and varied offices to which he was called by professional brethren and by fellow-citizens.

"It belongs to others to fill up the record of his

eminently useful life and his many beneficent efforts in the profession and in the community in which he dwelt. The members of this Society, notable in their confraternity, would hereby give utterance to their deep sense of the loss the Society has sustained, and indicate their individual sadness in the ever intruding thought, as they severally go about the streets, that they shall see his face no more."

CHARLES W. TOWNSEND, M.D., *Secretary.*

#### RESOLUTIONS OF THE NEW YORK OBSTETRICAL SOCIETY ON THE DEATH OF DR. FORDYCE BARKER.

*Resolved*, That by the death of Dr. Fordyce Barker the New York Obstetrical Society has sustained the loss of its oldest and most eminent Honorary Fellow, who, though prevented in recent years, by reason of his failing health, from taking an active part in its scientific work, always maintained a lively interest in its proceedings and rejoiced in its prosperity.

*Resolved*, That the Fellows of this Society, recalling his numerous acts of kindness toward them individually, feel that when his great warm heart ceased to beat they lost not only one who was the finest type of professional honor and dignity, but a long-tried personal friend.

*Resolved*, That they will cherish his memory as that of a wise physician and a chivalrous, high-toned gentleman, whose name will ever remain a synonym for all that is best and noblest in our profession.

*Resolved*, That we respectfully tender to the family of the deceased our sincere sympathy, and that copies of these resolutions be sent to them and published in the various medical journals.

For the Society,

THOMAS ADDIS EMMET, M.D.

WILLIAM M. POLK, M.D.

JOSEPH E. JANVIER, M.D.

HENRY C. COE, M.D.

#### PRESCRIPTIONS.

**CHAFING OF TRUSSES.**—DeGarmo<sup>1</sup> highly recommends the following, not only for use with trusses, but wherever a toilet-powder is used for children:

R Amyli	. . . . .	3 iv.
Creta gallica	. . . . .	3 ii.
Alum. ust.	. . . . .	aa 3 ii.
Acid. borac.	. . . . .	aa 3 ss.
Acid. carbolic	. . . . .	aa 3 ss.
Ol. leucis	. . . . .	aa 3 ss.

Sig. Powder very fine.

Where an abrasion has once occurred and is slow to heal, on account of the constant wetting by the urine and the irritation of the truss, the author has found nothing better than the balsam of Peru.

**VOMITING OF PREGNANCY.**—Gotschalk<sup>2</sup> has, in some severe cases where other methods have failed, obtained very good results from menthol.

R Menthol	. . . . .	1 part.
Alcohol	. . . . .	20 parts.
Aque	. . . . .	150 parts.

A tablespoonful every hour.

**STAINING SECTIONS.**—Zacharias<sup>3</sup> finds that the finest cellular structures may be rendered visible by coloring them with an ammoniacal solution of carmine,

to which a surplus of acetic acid has been added, and afterwards allowing them to remain for two to ten hours in a weak solution of ferric sulphate. This is a very useful method for bringing into view the nuclei of many zoölogical and botanical objects. The black coloration appears to be quite durable.

**LARYNGEAL CROUP.**—Betz<sup>4</sup> reports a case in which typical symptoms of laryngeal croup was very much improved in six hours by the following:

R Sulphuric ether	. . . . .	30 parts.
Acetic ether	. . . . .	10 parts.
Menthol	. . . . .	1 part.

Three drops inhaled from a chloroform inhaler every fifteen minutes.

**PYOKTANIN.**—Korn<sup>5</sup> recommends the use of this antiseptic in the form of powder for the same class of cases in which iodoform is now used. It is especially useful in suppurating wounds and ulcers. Whenever possible the surfaces should be dusted with the powder. Abscess walls and fistulous tracts should be brushed over with the pyoktatin pencil.

**ERUCTIONS.**—Hare<sup>6</sup> gives the following for atonic or subacute gastric catarrh, with belching:

R Oleoresin. capsici	. . . . .	guts. x or xx.
Pancreatin	. . . . .	gr. xx.
Pulv. zingiberis	. . . . .	gr. xl.
Pulv. carbon. ligni	. . . . .	gr. xl.
Fl. pil No. XX.	Sig.	One or two t. d.

**ASTHMA.**—Brubaker<sup>7</sup> is said to recommend the following:

R Liquor potassii arsenitis	. . . . .	guts. ij.
Potassii iodidi	. . . . .	gr. x.
Syrup. tolu	. . . . .	aa 3 ss.
Aqua	. . . . .	M.

This dose three times a day.

**BLUE OINTMENT IN DIPHTHERIA.**—Sinakowsky<sup>8</sup> has obtained very good results in diphtheria with inunctions of unguent hydrarg. Different parts of the body are anointed every hour until constitutional effects are produced. In addition, gargles of chlorate of potash are prescribed.

<sup>1</sup> Memorabilien, April 18th.

<sup>2</sup> Berliner klin. Woch., Feb. 9th.

<sup>3</sup> Practical Therapeutics.

<sup>4</sup> Col. and Clin. Record, May, 1891.

<sup>5</sup> Semaine Méd., No. 9, 1891.

#### METEOROLOGICAL RECORD,

For the week ending May 30, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Date.	Baro- meter		Thermo- meter		Relative humidity.		Direction of wind.		Velocity of wind.		Wet'r. °		Rainfall inches.

Deaths reported 2,774; under five years of age 969; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fevers) 465, acute lung diseases 463, consumption 336, diphtheria and croup 105, typhoid fever 103, scarlet fever 85, diarrhoeal diseases 69, measles 37, cerebro-spinal meningitis 21, whooping-cough 19, erysipelas 18, malarial fever 4.

From diarrhoeal diseases New York 18, Chicago 13, Nashville 11, Philadelphia and Charleston 6 each, Cleveland and Lowell 4 each, Lawrence 3, Brooklyn, Washington, Cambridge and Hyle Park 1 each. From measles New York 15, Chicago 11, Brooklyn 10, Washington 2, Cincinnati 1. From cerebro-spinal meningitis Chicago 8, New York 7, Washington 2, Brooklyn, Nashville, New Bedford, and Taunton 1 each. From erysipelas Boston 5, New York and Chicago 3 each, Philadelphia 2, Brooklyn, Cleveland, Washington, Nashville and Lynn 1 each. From whooping-cough Philadelphia 6, New York 5, Chicago 3, Nashville 2, Brooklyn, Cleveland and Washington 1 each. From malarial fever New York 1, Charleston 1.

In the twenty-eight greater towns of England and Wales with an estimated population of 10,010,426, for the week ending May 16th, the death-rate was 30.1. Deaths reported 5,542; acute diseases of the respiratory organs (London) 620, whooping-cough 167, measles 101, diarrhoea 45, fever 31, diphtheria 32, scarlet fever 19.

The death-rates ranged from 16.1 in Hull to 51.6 in Huddersfield, Birmingham 33.4, Bradford 50.0, Leeds 43.5, Leicester 40.2, Liverpool 29.8, London 26.1, Manchester 41.9, Newcastle-on-Tyne 27.2, Nottingham 26.7, Sheffield 39.5, Sunderland 23.3. In Edinburgh 22.7, Glasgow 28.5, Dublin 25.5.

In the twenty-eight greater towns of England and Wales with an estimated population of 10,010,426, for the week ending May 23d, the death-rate was 28.7. Deaths reported 5,542; acute diseases of the respiratory organs (London) 601, whooping-cough 145, measles 102, diphtheria 26, diarrhoea 30, scarlet fever 24, fever 24.

The death-rates ranged from 17.0 in Brighton to 50.4 in Nottingham, Birmingham 31.5, Bradford 43.0, Huddersfield 31.0, Leeds 35.1, Leicester 28.7, Liverpool 32.6, London 25.9, Manchester 41.0, Nottingham 26.7, Sheffield 26.3, Sunderland 25.2. In Edinburgh 23.5, Glasgow 26.5, Dublin 20.8.

## DEATH.

JOSEPH P. LOUIS, M.D., Editor of the Atlanta Medical and Surgical Journal, died in Atlanta, Ga., June 2d, aged seventy.

## OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MAY 30, 1891, TO JUNE 5, 1891.

Leave of absence for twenty days is granted Major WILLIAM E. WATERS, surgeon, U. S. Army. S. O. 122, Par. 6, A. G. O., May 28, 1891.

By direction of the Secretary of War, Captain JEFFERSON R. KEAN, assistant surgeon, is assigned to temporary duty at Fort Myer, Va., until the return of Major ROBERT H. WHITE, surgeon, to duty at that post. S. O. 122, Par. 8, A. G. O., May 28, 1891.

Captain EDWARD C. CARTER, assistant surgeon, will proceed, without delay, to Fort Canby, Wash., and report to the commanding officer for temporary duty, relieving Major JOHN D. HALL, surgeon, who will proceed to Fort Sherman for duty as post surgeon. S. O. 74, Par. 1, Department of the Columbia, May 22, 1891.

Leave of absence for one month is granted Captain JEFFERSON R. KEAN, assistant surgeon, to take effect after the return of Major ROBERT H. WHITE, surgeon, to duty at Fort Myer, Va. S. O. 123, Par. 1, A. G. O., May 29, 1891.

With approval of the Secretary of War, leave of absence for three months, to take effect on or about June 15, 1891, is granted Major DAVID L. HUNTINGTON, surgeon. S. O. 124, Par. 2, A. G. O., June 1, 1891.

By direction of the Secretary of War, the extension of leave of absence, on account of sickness, granted Captain HENRY P. BIRMINGHAM, assistant surgeon, in Special Orders No. 108, May 12, 1891, from this office, is further extended to June 21, 1891, on surgeon's certificate of disability. S. O. 125, Par. 6, A. G. O., June 2, 1891.

By direction of the Secretary of War, paragraph 1, Special Orders 74, May 22, 1891, Department of the Columbia, transferring Major JOHN D. HALL, surgeon, from Fort Canby, Wash., to Fort Sherman, Idaho, is confirmed. S. O. 126, Par. 4, A. G. O., June 3, 1891.

By direction of the Secretary of War, Captain VAN R. HOFF, assistant surgeon, is relieved from duty as a member of the Board of Medical Officers, to which he was assigned by paragraph 6, Special Orders 78, April 7, 1891, from this office, and will, upon the completion of the duties assigned him by paragraph 6, Special Orders 110, May 14, 1891, from this office, return to his proper station, Fort Riley, Kan. S. O. 126, Par. 11, A. G. O., June 3, 1891.

## OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JUNE 6, 1891.

C. U. GRAVATT, surgeon, detached from Naval Hospital, Yokohama, Japan, and ordered home.

FRANKLIN ROGERS, surgeon, detached from special duty, Norfolk, Va., and to Yokohama Hospital.

## OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE, FOR THE TWO WEEKS ENDING JUNE 6, 1891.

FRESKENDEN, C. S. D., surgeon. Granted leave of absence for thirty days. June 6, 1891.

IRVING, FAIRFAX, surgeon. Leave of absence extended seven days. June 4, 1891.

MEAD, F. W., surgeon. When relieved at Chicago, Ill., to proceed to Washington, D. C., and report to the Supervising Surgeon-General for duty. May 29, 1891.

MAGNUER, G. M., passed assistant surgeon. Granted leave of absence for five days. June 1, 1891.

YOUNG, G. H., assistant surgeon. Leave of absence extended fifteen days, on account of sickness. June 6, 1891.

## MASSACHUSETTS VOLUNTEER MILITIA. BOARD OF MEDICAL OFFICERS.

There appeared before the Board this day (June 6, 1891), Lieutenant J. E. Simpson, of Salem, who was duly examined and qualified as assistant surgeon, Eighth Regiment Infantry, Second Brigade. Lieutenant Silas G. Sawyer, of Alston, was examined, qualified and recommended for "assignment to temporary duty" as veterinary surgeon, First Battalion Light Artillery, First Brigade. To appear before the Board at a later date.

## APPOINTMENTS.

Drs. Francis H. Williams and E. M. Buckingham have been appointed Associate Visiting Physicians at the Boston City Hospital.

Dr. Vincent V. Bowditch has been appointed Physician to Medical Out-Patients at the same institution.

## Address.

JAMES THACHER, M.D., OF PLYMOUTH, MASS.<sup>1</sup>

BY JAMES B. BREWSTER, M.D., OF PLYMOUTH, MASS.

(Continued from No. 24, page 573.)

His labors as a teacher were no inconsiderable part of the good work which he performed for the advancement of his profession. Indeed, so remarkable habits of industry and application had he, that he even was able among his other duties to take up medical authorship, and in this field he accomplished a work, which for its extent and value must challenge our respect and admiration.

His first publication was entitled "The New Dispensatory, compiled from the most approved authors, both European and American," and was published in 1810. This volume he most courteously dedicated to his former preceptor, John Warren, M.D., Professor of Anatomy and Surgery in the University of Cambridge, and President of the Massachusetts Medical Society. Before publishing the work, he loyally submitted it to the Massachusetts Medical Society for its approbation. A committee consisting of Drs. John Warren, Aaron Dexter, and Josiah Bartlett, after examination, commended it in the following terms: "As it appears to have been a principal object of Dr. Thacher to adapt the work to American practice, and as he has adopted for the basis of his work the American Pharmacopoeia of Massachusetts, lately published by the Medical Society, and recommended for general use, they are of the opinion that it will co-operate with the views of the Society in that publication, especially as its nomenclature and order of arrangement seem to be strictly observed in the manuscript. They therefore conclude that it will be for the interest of medical science in this country to encourage the work; and it may be the means of exciting a more general attention to the medical virtues of American productions, many of which might be introduced into the materia medica, and advantageously as well as economically supply the places of foreign articles."<sup>16</sup> That these gentlemen did not err in their estimate of the book, or the need of the profession for such a work, is assured by the fact that it rapidly passed through four editions. The profession of the State showed an appreciation of it which must have been gratifying to its author.

Two years later he issued an octavo volume, entitled "Observations upon Hydrophobia." The style is that of a series of letters addressed to a friend, containing a very full description of the disease, the various theories and methods of cure existing at that time, and an inquiry as to the specific remedies which had been suggested,—most of them secret remedies, acquiring great fame as infallible cures. Among these last were the common red chick-weed, tree box and skull-cap,—each celebrated. The most curious of all was known as "Crouse's remedy," which was purchased from John M. Crouse, its inventor, by the New York Legislature, in the year 1806.<sup>17</sup> The recipe, as filed in the comptroller's office of the State of New York, is as follows: "First. Take one ounce of the jaw-bone of a dog burned and pulverized, or powdered to a fine dust.

Second. Take the false tongue of a newly foaled colt, let that be also dried and powdered. Third. Take one scruple of the verdigris which is raised on the surface of old copper by lying in moist earth. The coppers of George I or II are the purest and best. Mix these ingredients together, and if the patient be an adult let him take the common teaspoonful a day, and so in proportion for a child, according to its age. If these should fail, the patient should immediately apply to a physician, who will administer three drachms of verdigris and one ounce of calomel at one dose, and he need not be alarmed on account of the size of the dose."

After enumerating and pronouncing futile all the so-called remedies and plans of treatment which had then been suggested, Dr. Thacher, in his final chapter, expresses great hope in results to be obtained by properly conducted experiments upon animals in some suitable institution, and concluding, says: "You may smile at my project; but however chimerical and visionary it may appear, I would rejoice to be the Jenner of the proposed institution." This language, in the light of the researches and discoveries of Pasteur, seems now to have been almost prophetic.

In 1817 he published a work on the theory and practice of medicine, entitled "American Modern Practice; or, a simple method of prevention and cure of disease, according to the latest improvements and discoveries; comprising a practical system adapted to the use of medical practitioners of the United States; to which is added an Appendix containing an account of many domestic remedies recently introduced into practice, and some approved formulæ applicable to the diseases of our climate." In his preface he says, "It is confessedly a matter of regret that a country, in which literature and science have been so honorably and successfully cultivated, should so long remain destitute of a systematic work on practical medicine." The author most ably supplied this need, a second edition having been required a few years later.

In the chapter upon the character, qualifications and duties of a physician, the standard which he offers might well serve for the emulation of any generation. The entire literature of medicine furnishes no more complete or concise statement of the rules which should govern the conscientious physician who desires to do his full duty toward his clients and his fellow-practitioners. He says:

"The man who maintains this important station in society should possess the strictest integrity of character; disinterested benevolence and philanthropy should be interwoven in the constitution of his nature. He should possess that modesty and humanity which melts at every distress, extending the hand of relief and comfort to the afflicted, especially to the widow, to the fatherless and to him that hath none to help him. He should be actuated by the dictates of tenderness and sympathy, which have their origin in the best feelings of the heart. To these meritorious qualities should be added an acute, penetrating genius, a retentive memory, intuitive discernment, and an intrepid and decided disposition of mind. To excel in the profession of medicine requires indefatigable industry and a vast variety of liberal accomplishments, as well as an understanding improved by experience. The physician, on the commencement of his functions, should not allow his mind to be enslaved by systems, nor to imbibe a bigoted attachment to great names,—as there is no absolute perfection in systems, nor infallible

<sup>1</sup> Being the Annual Discourse delivered before the Massachusetts Medical Society, at the One-hundred and Tenth Annual Meeting, June 10, 1891.

<sup>16</sup> Preface to New Dispensatory.

<sup>17</sup> Observations on Hydrophobia, p. 208.

bility in the wisdom of men. He is not to be implicitly guided by the doctrines, nor the practice, of others, however eminent, but to establish a course of practice, the result of knowledge, founded upon experience and observation. He will avoid all appearance of vanity and ostentation, exhibiting, however, a modest confidence in his own merits that may command the confidence of others. In his prescriptions he will endeavor to combine simplicity with elegance, rejecting the absurd idea that a combination of many simples in one prescription may retain and exert the separate virtues of each. He will confide in a few selected articles judiciously adapted, that the indications may be answered by as few medicines as possible. A superficial or cursory view of the patient and a slight examination of the symptoms will never satisfy the inquisitive and intelligent physician, nor inspire confidence in his judgment and skill. The young practitioner will derive much benefit from a methodical record of all important cases that occur in his practice, describing with accuracy the disease, with the attendant symptoms and mode of treatment, whether successful or otherwise. Such record will furnish a document of much utility in facilitating his own improvement. It is to be recommended among the objects of peculiar importance to medical practitioners, to possess themselves of a well-chosen library. If the pecuniary resources of individuals are insufficient to procure a competent collection of books, let district associations be formed to accomplish this purpose. A social medical library would prove a bond of union among physicians, besides rendering the acquisition of knowledge cheap and easy to its members. Those who voluntarily preclude themselves from the refined pleasure and satisfaction derivable from professional study, and who practise only by rote, and dudge on in the same beaten track, although they may boast many years' experience, are but novices in many essential points, and utterly incompetent to discharge their calling with satisfaction to themselves or justice to their patients."<sup>18</sup>

No one can read even these brief extracts from Dr. Thacher's very full and complete article upon this subject without feeling that he was far in advance of his time in the exalted professional standard which he maintained, and in the high ideal which he urged, — an ideal which should stimulate the physician, not only to elevate himself, but also to contribute something to the general advancement of the noble calling to which he belongs. Who can doubt that, entertaining such sentiments, he was the good physician, honored and beloved for his good works? Dr. Thacher was at this time sixty-three years of age, and he was essentially a physician. The great work which he had accomplished as a practitioner, teacher and writer was confined to the field of medicine; but an imperfection of hearing, which he had from youth, increasing with advancing years, compelled him to relinquish attendance upon his patients, and to find employment for his active mind in other pursuits.

A distinguished member of this Society, in his annual address,<sup>19</sup> quotes the remark, "Successful men may have gained much to retire upon, but nothing to retire to, if literature, social ties and philanthropic interests have been lost sight of during the rush and struggle of their thirty years of active life"; but Dr. Thacher, never having been engrossed in his profes-

sion to the exclusion of all other subjects, now found occupation and enjoyment in literature, in agriculture, and especially in horticulture. He contributed much to the development of this branch, stimulating it both by his example and his pen, as he not only planted and trained orchards himself, introducing new varieties of fruit, but he wrote several papers upon the subject, and also a work entitled, "The American Orchardist," which passed through two editions.

In 1823, he published his "Military Journal, during the American Revolutionary War," which he dedicated, with sentiments of profound veneration for that patriotic warrior and statesman, to his Excellency John Brooks, Governor of Massachusetts. In this work we have one of the most graphic descriptions of the stirring scenes of the Revolution, faithfully portraying the hardships and struggles endured by those renowned patriots and heroes who risked life and fortune — everything but honor — in the cause of liberty. Thacher's Journal is a continuous narrative of events of which the author was an eye-witness, extending through the whole struggle for national independence, a period of seven and one-half years, written in a style easy and attractive, with that added charm which always attends the narration of personal experiences. Of all Dr. Thacher's works this is unquestionably the one which posterity has found the most valuable. Notwithstanding that it has passed through several editions, but few copies are now obtainable, and these are eagerly sought as rare prizes, by those acquainted with their value.

The next year after publishing his Military Journal, — being then (1824) seventy-two years of age — he issued in two volumes of more than seven hundred pages, "The American Medical Biography; or Memoirs of Eminent Physicians who have flourished in America," which he dedicated to Edward Augustus Holyoke, M.D., who was at that time in the one-hundredth year of his age, being the oldest physician in the United States, and who had been the first President of the Massachusetts Medical Society. In the preface of this work he makes acknowledgment for valuable assistance received in its preparation from a number of his professional brethren, — the only one of whom now living is the venerable Dr. George C. Shattuck. This work will never lose its value as a book of reference for all who may wish to learn of the distinguished men, who, from the time of the settlement of the country up to the date of issue, have advanced our profession. It contains a full and complete sketch of the lives of more than one hundred and sixty American physicians, most delightfully written, and honestly appreciative of the merits of each. A goodly number of portraits embellish the work, and help us to form an idea of those old worthies whom it commemorates.

An essay on "Ghosts, Demonology and Apparitions," and a "Practical Treatise upon the Management of Bees" followed soon after.

In 1832 he had become much interested in antiquarian research, and wrote the first history of the town of Plymouth. The first edition is said to have been burned while in the hands of the printer, and Dr. Dean, of Cambridge, believed that he possessed the only copy of this edition extant. In this volume he has collected the early records of the Pilgrims, and all events of interest from the landing of the Pilgrim Fathers down to the time of publication, very faithfully. It was the first town history published in this

<sup>18</sup> Thacher, Modern Practice, chap. x.

<sup>19</sup> R. M. Hild, M.D., before the Massachusetts Medical Society.

State, and is valuable for reference even now. It is probable that Dr. Thacher was led to undertake the task from an interest inspired by his antiquarian researches in connection with the Pilgrim Society, of which he was one of the earliest members, and for many years librarian, and custodian of its collection, — a position filled by him at the time of his death. The records of the trustees of the Pilgrim Society contain the following resolve :

"Resolved, That the members of this Society entertain a grateful sense of the eminent services of their late librarian, Dr. James Thacher, recently deceased, who, by his zeal and perseverance in promoting the objects of the Society, has well deserved that his memory be cherished with respect by all who feel an interest in its success."<sup>20</sup>

He was one of the earliest members of the Massachusetts Medical Society, for many years serving as councillor. Its objects and interests were ever dear to him, and he always expressed the greatest confidence in its continued success. He was also honorary member of Medical Societies of Rhode Island, Connecticut, New Hampshire and Georgia. He was elected a member of the American Academy of Arts and Sciences, of the New York Historical Society, and the Historical Society of New Hampshire, and foreign member of the Society of Statistics of Paris. He received the honorary degree of Doctor of Medicine from Harvard University, and also from Dartmouth College; also the degree of Master of Arts from Harvard University. He was one of the original members of the Society of Cincinnati.

As a physician, Dr. Thacher was versed in the science of medicine. He delighted in books, and made great use of them, but he did not draw his information from these alone. He had a very extensive acquaintance among eminent men in many branches of science, and maintained with them a correspondence most unusual in those days. In the practice of medicine he was not hampered by traditions and dogmas, but was ever progressive, constantly seeking new suggestions, and ever ready to try legitimately new plans of treatment. Sometimes his zeal for improvement in therapeutics caused his rivals unjustly to charge him with credulity, and too great haste in the adoption of new ideas.

Piety was a marked trait in his character; in all his writings he expresses the most profound respect for religion. He strictly and religiously regarded the Sabbath, refraining from all unnecessary professional labor upon that day, and was constant in his attendance at public worship. All social reforms found an earnest advocate in him. Intemperance he especially denounced; and the smoking and chewing of tobacco he declared to be nauseous and disgusting habits.

Indicating his antislavery views, we may quote from his *Military Journal*, an entry made in October, 1781, while he was a young man, acting as surgeon of the Revolutionary Army:

"The labor on the Virginia plantations is performed altogether by a species of the human race, who have been cruelly wrested from their native country and doomed to perpetual bondage, while their masters are manfully contending for freedom and the natural rights of man. Such is the inconsistency of human nature. Should Providence ordain that America should be emancipated from thralldom, it should in gratitude be our prayer, that the African slave may

be permitted to participate in the blessings of freedom."<sup>21</sup> This opinion he entertained and recorded, at a time when the right to hold human beings as slaves was unquestioned by even the most progressive and philanthropic.

As an author Dr. Thacher is justly entitled to an honorable position. The number and variety of his subjects is astonishing. He was an indefatigable worker, — thus he was able to accomplish so much literary work in addition to his strictly professional labors. His style was conspicuous for completeness of research and clearness of description, with an ease and flexibility which rendered it attractive. The more we reflect, the greater will be our surprise, that without the early advantages of a liberal education, and accomplishing his work at a distance from the few medical centres and libraries then existing, and unassisted by the interchange of opinion furnished by medical journals and the stimulating association with those engaged in like pursuits, and removed from every kind of assistance in which city life is so rich and country life so poor, — privations which every physician engaged in country practice must have often felt interfere with the fulfilment of his desires and aspirations, — that, notwithstanding all these disadvantages, his labors in the field of literature were eminently successful and the crowning glory of his life; for his last work was published when he was over eighty-one years of age.

His was a life of great activity and industry, — the venerable toiler not resting from his labors even at an age when repose from the cares and toils of life would seem to be imperatively demanded. His usefulness continued even to the end.

At ninety years of age he died, as the town record tells us, of old age, after a brief illness, upon May 23, 1844.

It is with great local pride that I have imperfectly traced the career of Dr. James Thacher, who resided for more than sixty years at Plymouth, believing that the name of this zealous patriot, good physician, faithful teacher and able author, deserves an honorable position upon the roll of eminent members which is the glory and honor of this Society.

### THE PATHOLOGY AND TREATMENT OF CHRONIC OVARITIS.

BY ALEX. J. C. SKENE, M.D.

THE study of the pathology of ovaritis derives a special interest from the fact that the ovary differs from all other organs of the body, in that its function is performed at the expense of a portion of its structure which is never restored to its original condition. The rupture of each Graafian vesicle in ovulation, causes the destruction of the vesicle. Rudimentary vesicles mature and repeat the function of their predecessors, and are in turn destroyed. Finally the supply ceases, and the ovary, worn out in structure, becomes functionally incompetent long before the general organization has reached the end of its life and activity. In all other organs of the body, function is effected through cellular disintegration and restoration.

<sup>20</sup> Records of Trustees, Pilgrim Society, May 27, 1844.

<sup>21</sup> *Military Journal*, p. 334.

This peculiarity in the natural history of the ovary makes it difficult for the superficial observer to distinguish between the normal degeneration, and the structural changes which result from chronic ovariitis. Experts also find it no easy matter to distinguish, by gross appearances, the atrophy of old age from the cirrhosis of inflammation.

In discussing the pathology of ovariitis, I shall briefly point out some of the established facts, which are of most interest in relation to the diagnosis and treatment of this affection, and omit all that is ill-defined, uncertain, and of little interest to surgeons.

The pathology of ovariitis is characterized by changes of structure, brought about chiefly by areolar hyperplasia first, then by atrophy of the normal tissues, and finally by a condition of cirrhosis. In this respect the morbid process and its products more resemble degeneration than an inflammation such as is observed in other organs. It is more like certain forms of chronic nephritis in the natural history of its pathology. Owing to these peculiar and distinguishing features, the affection has little in common with acute puerperal or non-puerperal ovariitis, or with secondary acute ovariitis due to peritonitis, and therefore all such conditions will be carefully excluded from the discussion of the subject in hand.

The first variation from the normal towards the pathological is deranged innervation; the ovary, owing to its important office and intimate relations to the other organs, being peculiarly prone to reflex disturbances. These, though temporary as a rule, when oft repeated and prolonged in duration induce changes in the circulation, which impair nutrition and finally produce changes of structure. This ovarian hyperæmia, the first step in the process, may subside and complete recovery follow. Reliable evidence of this has been obtained, first by clinical observation of cases which gave all the signs and symptoms of ovarian congestion, and which, under careful management, completely recovered. Secondly, by inspection after laparotomy. I have not infrequently found a prolapsed, tender and painful ovary which, upon inspection, after opening the abdomen, was markedly hyperæmic, but presented no apparent change of structure, except œdema. After fixing it in place by stitching the utero-ovarian ligament to the upper border of the broad ligament, the signs and symptoms have all subsided. The continuation of the hyperæmia slowly produce those structural changes which are invariably affected by prolonged malnutrition. The first noticeable changes take place in the blood-vessels themselves. They become dilated and a peculiar degeneration of their walls occur. These changes have been elaborately studied by Dr. E. Nœggerath; he advanced the idea that these vascular changes were closely related to the genesis of ovarian cystomata. This may be true in certain cases, but it more frequently ends in hyperplasia of the stroma which gradually goes on, and in time crowds out all the normal structural elements of the ovary. Finally, a true cirrhosis is produced. With these changes in the blood-vessels, the circulation is interrupted to a degree that causes œdema, which increases the size of the ovary and renders it softer. Apoplexies sometimes occur, and occasionally one or more of the blood clots may be seen near the surface. These conditions can be distinguished from a diseased vesicle by the fading of the tissues around the clot. This last-mentioned lesion occurs in the early stage of the ova-

ritis, and gradually disappears as the process of hyperplasia proceeds to a complete cirrhosis. These changes explain some of the important facts in the clinical history. The ovary which is found enlarged, softened and tender to the touch, will, in months afterward, appear subnormal in size. Likewise the same lesions may be recognized upon inspection after laparotomy, if one has become familiar with them by previous study.

While hyperplasia of the stroma is going on, the follicular elements undergo certain changes. The contents of the follicles become cloudy from degeneration of the epithelial elements. The gross appearance of the ovary at this time would lead one to suppose that there were a number of vesicles approaching maturity, but the uncommon number of these distended vesicles is evidence that they are abnormal.

The full value of a knowledge of the gross pathology of ovariitis can be fully estimated by those who have mistaken the normal for a pathological degeneration of the ovaries, and have removed them, to learn subsequently, through the microscopist, that they were not diseased. I well remember hearing an interesting discussion regarding cases in which one ovary has to be removed for advanced disease. The question was: Should the other ovary be left or removed if there is no positive evidence of its being diseased? Much was said, pro and con, but not a word was uttered about how to detect pathological changes which should decide the matter. The morbid appearances which aid the surgeon in deciding when to remove an ovary and when not to remove it are as follows:

Follicles which, from their size, number and dark color are evidently diseased, should be removed. Enlargement, congestion and softening from œdema, and patches of induration with irregular distention of the vessels and the evidence of small blood-clots as described above, are conditions indicating removal.

Cirrhosis, indicated by subnormal size, induration and rough surface, when found in a young subject, can be easily passed upon. But in a subject near or after the menopause, this appearance of the ovary does not decide with certainty whether there is cirrhosis or simply senile atrophic degeneration.

I have thus briefly described this part of the subject, introducing only such facts as I have obtained from observation, and which have appeared to be of possible use in guiding the surgeon. This brevity arises in part from my limited knowledge, but mostly from the hope of raising a discussion which will doubtless bring out much that we need to know. Much might be said about the influence of chronic ovariitis upon the functions of the sexual organs and the nutritive and nervous systems, but time will only permit me to say, that menstruation is often deranged, and in various ways. Dysmenorrhœa is often present, and in some the menses are retarded and scanty, while in others too frequent and profuse. When the latter condition exists, the ovariitis is more easily controlled than in patients who have a scanty flow.

The effect upon the nervous system is peculiar and marked. Depression and irritability are usually pronounced. The hystero-epilepsy which has attracted much attention from the neurologists, is really an epileptiform affection, due, in all cases that I have seen in my own practice, to ovarian disease. Ovariitis also ranks first among all diseases of the sexual organs in the causation of mental disorders.

The causation of chronic ovaritis demands a brief notice, owing to its intimate relation to the question of treatment. According to my observations, the cause which most frequently obtains is imperfect menstruation. When the uterus is undersized or flexed forwards and backwards, and the menstrual flow scanty and attended with pain, the ovaries are liable to take on chronic inflammation. This is far more liable to occur if the sexual function is perverted in this class of subjects. Specific causes, such as produce the eruptive fevers, are said to affect the ovaries; but I believe that acute ovaritis is more liable to occur under these circumstances. It is probably true, also, that gonorrhœa causes acute rather than chronic ovaritis.

The strumous diathesis (which I understand to be that condition of organization which invites tuberculosis), predisposes to chronic ovaritis, and inherited or acquired syphilis does likewise.

Much has been written about endometritis as a cause of ovaritis, upon the ground that the structure of the endometrium and ovaries have a common embryonic genesis, and the fact that the two diseases are often found together; but this is still an open question.

In regard to the diagnosis of chronic ovaritis, I refer all interested to the able paper on the subject by my esteemed friend, Howard A. Kelly, in the *American Journal of Obstetrics* for February, 1891.

#### TREATMENT.

The advancement of abdominal and pelvic surgery in recent times has led to the removal of the ovaries as the most prompt and effectual treatment of chronic ovaritis. There are reasons for this upon theoretical grounds. The ovary is causing much suffering; there is a likelihood that it will be a long and tedious trouble, especially is this the case if general treatment has failed; the ovaries are not necessary to existence, and can be removed with safety; it is according to the rules of surgery to remove any organ, or other portion of the body that one can live without, in case a disease of the part tends to take life or cause unlimited suffering and invalidism. Hence, from this way of looking at the matter, the ovaries should be removed.

The facts are (facts that have been proven almost sufficiently), that chronic ovaritis does not end fatally, and is self-limited though often of long duration; the removal of the ovaries is not free from all danger, though all cases properly operated upon have recovered, and it does not in all cases give complete relief. In fact, many of the cases are not much improved, if any; even those who are nearing the menopause, and who bear the loss of the ovaries better than younger subjects, occasionally suffer much from those nervous disturbances which follow an abrupt menopause, and have to endure pelvic pain in the region of the stumps. The clinical history of cases in which the ovaries have been removed does not, in all cases, show great advantage over those in which the ovaries are left to complete the natural history of the disease. Younger subjects do not bear the loss of their ovaries agreeably. Some become fat, indolent, inefficient, and subject to headaches. Others are irritable, dyspeptic and despondent, while but few enjoy good general health and mental vigor. This statement is contrary to much of the published literature, but is closer to the

actual facts. The cases cured are those operated on when near the menopause; those who are improved are generally those who suffered from complicating affections, such as dysmenorrhœa; while the unimproved are the younger subjects, in whom the disease was uncomplicated.

The objections to surgical treatment apply to the removal of both ovaries. In cases in which one ovary alone is affected, and especially where there is prolapsus of the affected ovary and retro-displacement of the uterus, ovariectomy is perfectly satisfactory. The removal of the diseased ovary gives relief and the retro-displaced uterus can be restored, while the remaining ovary performs its functions, and the general health of the patient is preserved. I desire to be understood as advocating the removal of the ovary only when there are structural changes from inflammation and prolapsus at the same time. Prolapsus can be relieved by fixing the ovary to the upper border of the broad ligament, and the welfare of the patient can be thus conserved to a higher degree. When advocating conservative measures in regard to abdominal and pelvic surgery, it may be inferred that I am behind the age in experience; but I have had a large field for operative surgery, and have acted to the fullest extent justifiable, according to my judgment. In fact, I have in the past violated the rules I now advocate, but I have not been satisfied to have my patients simply survive the operations. I require that they be cured, and failures in this regard have led, I trust, to a rational conservatism.

I have no word of condemnation for those who have removed, and are still removing, ovaries for the relief of chronic ovaritis. Their work, while not always beneficial, has been of vast interest to science. Their doings help to perfect surgery. The rough, unsightly scaffolds employed by builders are temporary necessities, which are all cleared away when the structure is perfected and completed. In like manner the heroic, daring experiments of the surgeon are valuable stepping-stones, which lead to mature science and art.

The indications for general treatment are to lessen the blood-supply, and relieve pain by correcting the deranged innervation. This demands rest in the recumbent position in the early stages. At the same time general exercise should be enjoyed, either by massage or gymnastic exercise, in the reclining position. I specially desire to commend systematic calisthenics, in the recumbent position, as a most valuable aid in improving or maintaining the general health in many diseases of the pelvic organs which require rest as an important part of the treatment. The condition of the digestive organs should be carefully watched. The poor appetite, coated tongue and constipation; or the capricious appetite, flatulence and occasional diarrhœa, can be relieved by a number of small doses of mercury and a laxative. The saline laxatives are the best when they act without causing flatulence. The use of Saratoga waters often gives good results by improving digestion and keeping the portal circulation active. By keeping up a free elimination by the bowels and kidneys much benefit is obtained.

This applies in cases that are apparently debilitated. Many times I have taken cases away from tonics, stimulants and forced feeding, and given saline laxatives, with the effect of increasing the patient's strength. To relieve the pain and lessen the hyperæmia, the

bromide of sodium and fluid extract of hydrastis canadensis, are by far the most potential agents that I have found; they are given in combination and in doses sufficient to produce the desired effect. Twenty to thirty grains of the bromide and ten to twenty minims of the hydrastis, three times a day, until the physiological effects of the bromide are noticed in a mild degree. If the hydrastis is given alone, in such doses, it sometimes causes pelvic pain of a dull character, but when combined with the bromide it has no such effect. These agents are most efficacious in the beginning of the attack, and hence they should be discontinued as soon as the pain is relieved in a marked degree. Should the pain and tenderness return at the succeeding menstrual periods, the bromide and hydrastis should be resumed. In some cases, much larger doses of bromide are required, and in others it fails altogether to relieve pain. Then it is necessary to employ other agents especially during menstruation. Ten grains of salicylate of soda and five of antipyrine given between meals and in the night when the stomach is empty, answers for some; others, more especially those markedly debilitated, do better on full doses of aromatic spirits of ammonia, camphor and chloric ether, with small doses of cannabis indica. This combination is best suited to those who get relief from gin and whiskey, but it is to be preferred as alcoholic stimulants ultimately do harm, though they may give temporary relief. Direct or local treatment should be adapted to the social state of the patient, and the presence or absence of complications such as endometritis. In the unmarried local treatment is often injurious. In fact, in such cases, it is better to avoid any examination of the pelvic organs, if the history is sufficiently clear to enable one to make a diagnosis with reasonable certainty. Hot Sitz bath, counter-irritation and hot vaginal douches, the latter to be employed by a competent nurse, comprise about all that I employ in the way of direct treatment. The vaginal douche should not be continued unless it is decidedly sedative in its effects. In married women (and those who are so in all but the name) local treatment is more valuable. The treatment of any disease or displacement of the uterus that co-exists should be managed in the usual way, and such local applications should be used as may aid in relieving the tender and hyperemic ovaries. I employ a small tampon or pledget of cotton or wool saturated with equal parts of the tincture of belladonna and glycerine, applied behind the cervix uteri, and permitted to remain forty-eight hours, and after its removal a hot douche. These are continued during the first days of treatment. The effect is to support or steady the ovaries, while the sedative effect of the belladonna and the depleting effect of the glycerine are obtained. This I have followed with applications of tincture of iodine after the manner of Dr. Emmet. Recently I have used, with good effect, the sulphur ichthyolate of ammonium, five parts in ninety-five of glycerine, applied in the same way as the belladonna and glycerine.

The general and local treatment, thus briefly outlined, gives relief from the more pronounced symptoms. The pain becomes less and the tenderness also. The general health improves and the pelvic congestion subsides. This is apparent in the color of the mucous membrane, the improved menstrual functions and diminished leucorrhœa. Then the local treatment may be employed at longer intervals or sus-

pended altogether. The constitutional treatment should now be modified. Tonics and laxatives may still be required, but alteratives are also indicated. Iodine and mercury are the chief agents. They act upon the ovaries, as they do upon all glandular organs, and modify or arrest the morbid histological changes which take place slowly. Small doses of bichloride of mercury, with chloride of iron, when iron is indicated, followed by syrup of the iodine of iron in doses as large as can be borne. These can only be used when the bromides are given up. When giving these alteratives the patient often misses the bromides used to give sleep. Sulphonal, at such times, is of great value. In fact, it is the most potent sedative that is at the same time free from ultimate or after-effects that are unfavorable, that we have in gynecological practice. When a sedative is required while iodine of mercury is being used, I find ten grains of salicylate of sodium and five grains of antipyrine, given three times a day an hour before meals, give much relief, especially in those who suffer from nervous dyspepsia and flatulence.

One important element in the treatment is patience and careful watching. Improvement comes and the patient or the physician gives up treatment, and there is danger of relapse. The poor in hospitals often suffer for want of time for prolonged treatment, and this often tempts the surgeon to seek more prompt relief by removal of the ovaries. This does not apply with the same force to those who have time and means to secure the needed care.

## PULMONARY SYPHILIS IN THE ADULT<sup>1</sup>

BY THOMAS E. SATTERTHWAITE, M.D., NEW YORK CITY.

(Continued from No. 24, page 576.)

At this point it is proper to state that Dr. Porter called attention some years ago to a hyaline change in the vessels in syphilis, and Drs. Councilman and Welch have recently corroborated his statements. But as syphilitic lung affections are of such various sorts simulating in a wonderful manner the lesions of tuberculosis, whether we refer to the larynx, bronchi, parenchyma of the lungs or the pleure; so the signs derived from these morbid states cannot be very different from those of tuberculosis in the same parts. And hence it is, that we may justly expect the same class of clinical signs. Thus laryngitis will often precede the lung trouble, and a certain amount of bronchitis may be expected. Rapid breathing and dyspnoea I have found quite common. But it is notorious that we may not be able to detect the cause of the trouble either by auscultation or percussion; though judging from our post-mortem records it is proper to suppose that a certain amount of deposit has then taken place while our ear detects merely the sibilant and sonorous rales of bronchitis. Cough is also an early symptom. Expectoration is slight at first; in advanced cases copious. Hemoptysis, I believe to be rare, and night sweats are uncommon; as would be inferred from the general absence of much suppurative change in the lungs. Even in advanced cases emaciation is infrequent, and this symptom contrasts strongly with fibroid tuberculo-

<sup>1</sup> Read before the New York Academy of Medicine, Section of General Medicine, May 19, 1891.

sis, where the emaciation and arching of the back are well-marked. When there is a wide dissemination of syphilitic tubercles, or where there are small gummy tumors, auscultation and percussion may fail to reveal anything; but so soon as fibroid induration has commenced, we should have the characteristic signs of beginning consolidation. It is generally supposed that syphilis elects by preference the middle and lower lobes of the lungs. This is true of gummy tumors, but not of the military deposits nor of the induration. In my opinion, they involve the upper lobes fully as frequently as they do the lower lobes, and in fact, we find the most positive signs first under the clavicles. Here, too, we find the first indication of cavities, unless they come from the softening of gummy tumors, but the cavities (especially those in the apices) are much smaller than in tubercular phthisis; often so small that they escape detection by the ear. The temperature rarely exceeds  $101^{\circ}$ , in this respect also, contrasting strongly with tubercular phthisis. But when the disease has advanced to the point where there are evidences of destructive changes, we have usually copious albuminuria and casts of all kinds with uræmic symptoms. At this point, too, we are apt to have some suggestive sign of brain implication, as shown by headache, delirium, convulsions, mania, paralysis or coma.

In this connection I must not fail to state that many of the criteria that have been given by writers for determining this disease relate not to it, but to its concomitant lesions. Thus, the nervous phenomena just mentioned do not relate to the lung affection itself, but to the cerebral lesions. So, too, the periostitis that has been relied upon in diagnosis is simply a common manifestation of constitutional syphilis. In making a differential diagnosis where gummy tumor or a localized deposit is suspected, we should remember its points of election, and then exclude ordinary bronchitis from a cold, or broncho-pneumonia from a similar cause, or from inspiration of a foreign body. In interstitial thickening, we should exclude fibroid phthisis and the chronic hyperæmia of heart disease. In examination of the lung, we should exclude ordinary tubercular (so-called catarrhal phthisis) after careful microscopic examination of the sputum. Of course, the difficulty of apprehending the relation of syphilis to the lung trouble becomes greater when we realize that in about half of the cases of syphilitic lung disease, pulmonary tuberculosis is closely associated; and yet in these very cases, in knowing the potency of specific remedies, we may feel that we can palliate if we cannot arrest. And this brings us in conclusion to the prognosis, which I may say (in uncomplicated instances) is favorable, just in proportion to the stage at which we made our diagnosis.

I am a firm believer that syphilis is a disease not only amenable to treatment in all stages, but capable of being arrested and held in check in almost all cases at any time before destructive changes have taken place. As in tubercular phthisis, we cannot restore a tissue that has become necrotic; but even then elimination of the morbid products and cicatrization are still possible. Hence, up to the stage of softening, specific remedies will act promptly and well. I have had satisfactory experience on this point, and only regret that the lesson came to me so late in life.

There is one point to be remembered in the treatment, which is, that in lung syphilis, as in other forms

of visceral syphilis, all remedies, whether iodides or mercurials, should be pushed actively from minor doses to the limits of tolerance, if we expect the most successful results. These remedies we *have* to use in ordinary practice, and they rarely disappoint us, if given with ordinary discrimination; but they should not be employed to the exclusion of proper hygienic measures, such as physical exercise, hydro-therapeutics and a well-regulated dietary, which latter, without drugs, will sometimes accomplish wonders for the patient.

In closing this paper I venture to state that pathologists in general and clinicians as well, have not heretofore realized the importance of recognizing pulmonary syphilis. But personal experience for a few days in such instances, with iodides in proper doses, or even with mercurials, will, I am confident, cause a change in opinion among the members of our profession, and the points that I have emphasized will be sustained. Thus it will be seen that in making a diagnosis in chronic pulmonary complaints subjective symptoms have to be considered calmly, deliberately and without prejudice; that the signs of general constitutional syphilis must ever be present in one's mind; while the physical signs detected by auscultation and percussion, have only a subordinate value.

CASE I. E. G., aged forty-nine, German marble-cutter, was admitted into hospital April 17, 1886. About three years before admission he began to be troubled with dyspnea, some precordial pain, cough and general indisposition, and quite lately œdema of the feet. Physical examination disclosed dulness at the right apex, large and small moist rales, with increased vocal fremitus. Expectoration abundant. The urine was of high specific gravity; albumen 20 per cent., hyaline and granular casts. Suspecting syphilis, the patient was put upon the iodide of potassium, in téngrain doses, three times a day. Further examination of the lungs, by the late Dr. McBride, revealed a peculiar sound, to the right of the sternum in the third space. It was heard during respiration, and ceased when respiration was suspended, but in quality it resembled a heart murmur. After stopping the nostrils and suspending the breath, and then admitting air, a splashing sound was heard, thought to be the splash of fluid against the walls of a cavity. Under treatment, the cough was improved and expectoration diminished. Subsequently, however, attacks of dyspnea supervened, and ultimately he died in uræmic coma.

At the post-mortem examination the heart was found very much enlarged, weighing seventeen ounces; its cavities were also dilated: both lungs were adherent to the chest walls, the right especially. In this lung was only one very prominent lesion, namely, a nodule upon the anterior surface of the superior lobe, about three inches from the apex; softening had taken place in the centre of the nodule, and the cavity that had been produced communicated with a bronchiole of considerable size. The interstitial tissue of the lung was much thickened, as in interstitial pneumonia, whether syphilitic or otherwise. The kidneys were the seat of chronic diffuse nephritis. The liver capsule was thickened; its surface was indented with clefts and fissures, and the vessels were enclosed in fibrous deposits,—all of which are prominent characteristics of syphilitic cirrhosis. There was marked adhesion of the dura

mater to the calvarium, with thickening and opacity of the pia mater. In other words, there was at first the clinical diagnosis of advanced lung syphilis, with relief to cough and expectoration by the internal administration of the iodide; and at post-mortem examination there were the evidences of general thickening of fibrous tissue in the meninges of brain, the liver, lungs and kidneys; but it would seem now to be a question whether the interstitial pneumonia may not have been primarily induced and maintained by the inhalation of marble dust, to which the patient had been exposed in his avocation as a marble-cutter. Certainly that is possible, while it is equally true that there were found multiple deposits of fibrous tissue such as are found in advanced tertiary syphilis.

CASE II. The following is a case that is in many respects analogous:

P. M., aged sixty-three, Ireland, groom, was admitted to hospital November 15, 1886. No history of syphilis or rheumatism obtained, but an admission of the alcoholic habit. He had asthma from childhood. Five months ago he was taken sick with cough, mucopurulent expectoration, dyspnea and loss of appetite; lately the urine had been scanty, and he had had edema. On examination, the patient was found suffering from dyspnea. Evening temperature  $101^{\circ}$ ; urine scanty, alkaline, specific gravity 1.012, albumen 20 per cent., blood, but no casts. Physical examination shows that heart apex is in the fifth space, four inches from the median line; impulse at apex diffused; aortic regurgitant murmur; pulse trip-hammer in character. Percussion discloses some dulness or wooden resonance in front, exaggerated resonance behind, with sonorous rales; liver enlarged; patient's condition one of marked stupor and prostration. At a late physical examination a probably tricuspid regurgitant was made out. The patient ultimately died of urinary suppression.

At the post-mortem examination it was found that the orifices of the aortic valve were extensively perforated, so as to produce insufficiency; the tricuspid also was much thickened; the heart weighed twenty ounces. Both lungs were bound firmly to the chest walls by old pleuritic adhesions; in the right were found several small bodies that looked like gummata, the tissue of the lungs was thickened; bronchi dilated. In the left lung there were several cheesy nodules near the apex; they were distinctly encapsulated, and liquefaction had commenced at their centres; thickening and dilation of the bronchi. The liver exhibited the indications of interlobular cirrhosis, and the capsule was marked by pits and depressions. The kidneys were small, and exhibited the gross and microscopic character of chronic diffuse nephritis; they also contained small nodules that were classed as gummata.

Here, then, we have an instance of several associated conditions. But I am of the opinion that the interlobular cirrhosis was unmistakably of syphilitic origin. The clinical signs as represented by cough, dyspnea, expectorations, diurnal elevation of temperature, disturbance of the digestive functions and mental weakness, sustained this view. That the patient denied syphilis is, I think, immaterial, in the face of the lesion in the liver. And yet I must admit, that the heart disease, congenital or acquired, the interstitial pneumonia and Bright's disease were in conjunction capable of explaining the clinical signs.

CASE III. The following case may be regarded as

a probable example of syphilitic abscess of the lungs, from the disintegration of gummy tumors.

T. N., aged thirty-five, was admitted into hospital September 22, 1873. During the previous year he had been under treatment in the same hospital for the initial lesion and secondary eruption; and subsequently he had been under treatment at one of the college clinics for prolonged and persistent headache. As no doubt was entertained as to his disease, iodide of potassium, in thirty-five-grain doses, was ordered three times daily; but nausea and vomiting followed, and anodynes were found necessary for the relief of the pain. A few days later the patient became hemiplegic on the left side, and later delirious. Under mercurial inunctions and the iodide (in one-drachm doses every four hours), the patient began to improve. Movements of the affected side became perceptible, and delirium disappeared during the daytime. After improving slowly for about ten days, the patient was again taken with vomiting and also with diarrhoea and delirium. The diarrhoea was checked, but the patient died comatose.

At the post-mortem examination, the liver was found small and cirrhotic, while the right lung contained three large abscesses that were filled with ichorous pus. The right pleural cavity also contained pus. It is fair to suppose that in this case of profound poisoning by syphilis, in which death seemed to have been caused by meningeal hemorrhage, and where the liver was cirrhotic, in fact, where lungs and liver exhibited lesions that are known to occur in syphilis, and while the clinical history points in the same direction; that the abscesses were also themselves syphilitic.

CASE IV. S. A. B., aged fifty-four, was admitted into hospital April 14, 1881. He was weak, anæmic, and somewhat disturbed in his mind. The year previous he had suffered from pneumonia, which had left him with a dry cough. Had never suffered from night sweats, pain in the chest, or hemorrhage. Admitted having had gonorrhoea, chancre and bubo in his youth. Physical examination was practically *nil*. On closer inquiry, it appeared that the patient had exhibited syphilitic manifestations, such as abscess of the tibia, ulcer of the bridge of the nose, and sores in the roof of the mouth. A week after admission, was taken with hæmoptysis, and suddenly died.

The lower lobe of left lung exhibited purulent infiltration; or rather it was riddled with minute abscesses. The base of this lung had a hob-nailed appearance, and each ulceration, when pricked, exhibited pus. Liver fatty and cirrhotic. At the post-mortem, I was at first inclined to think the case one of catarrhal phthisis (tubercular); but from a review of the case, and the absence of any tubercles, I am now inclined to think that it was a case of chronic syphilitic pneumonia.

CASE V. The history of the following case was furnished me by my friend, Dr. G. L. Peabody. I am responsible for the pathological findings.

The patient, a young man, age thirty-seven years, a painter, was brought into the New York Hospital in the autumn of 1887. He was suffering from an epileptiform attack, and had a blue line on the teeth, though not on the gums. Urine contained albumen. In a few days he left the hospital, feeling quite well. In January of 1888, he was again brought to the hospital in a convulsion, which was thought to be uræmic. Urine scanty, specific gravity 1.022, abundant albumen

and all kinds of casts. Edema of the lungs supervened, and death ensued from heart-failure.

At the post-mortem examination, the body was found thin, but not emaciated. No general dropsy, nor was there any abnormal collection of fluid, either in the thoracic or pericardial cavities. The lungs were not attached to the chest walls, except at the right apex. This apex showed signs of extensive interstitial deposit without pigmentation; it had the appearance of the "white pneumonia" of syphilis. Both lungs were œdematous. Heart was enlarged, and hypertrophy of the left ventricle was evident. There was fatty infiltration of both aortic and mitral orifices. Spleen normal in size and weight. Both kidneys were small and gray, and were examples of the atrophic form of chronic diffuse nephritis. No noticeable change in the thickness of the renal vessels. The liver was enlarged, dark in color, and was streaked by numerous white lines, following the course of the superficial vessels. The dura was thickened, and was adherent to the calvarium. Much serous fluid escaped in removing the skullcap. The pia was also thickened and opaque, the lateral ventricles had been dilated, and the foramen of Monroe was unusually large. The spinal cord gave evidence of commencing locomotor ataxia. All of the arteries examined were either fatty or calcareous.

Here, then, was a case, that, without the subjective history of syphilis, was, I think, a true example of pulmonary syphilis, judging from the combined evidence furnished by the meningitis, pulmonary thickening, vascular changes, and disease of liver and spinal cord; but the disease had not spent its chief weight on the lungs, although they were diseased.

CASE VI. A. N. L., sixty-seven years of age, a laborer, was admitted to the hospital on December 1, 1885. There was no hereditary syphilis or phthisis. When he was twenty years of age, he had rheumatism; and at about the age of fifty had paralysis of the left side, which continued for six years; but from which he entirely recovered, presumably under treatment in Ward's Island Hospital. Now suffers from dropsy of the feet; is constipated; physical examination of lungs and heart negative. Specific gravity of urine 1,020, albumen, pus. Condition continued about as above for about two weeks, when a severe headache set in. A week later it was discovered that he had double pleuritic effusion in the left side; aspiration, and seventeen ounces removed from left side. On the next day thirty-one ounces removed from the right. A few days later paralysis of the right leg occurred. Ten days later there was noted absence of superficial and deep reflexes. About this time he became unmanageable, and had to be removed from the ward. He died in coma, about one month after admission.

At the post-mortem examination the heart was found hypertrophied, weighing eighteen ounces; some fatty infiltration of the aortic and mitral orifices. The apex of the right lung was bound tightly to the chest walls. The upper lobe was the seat of marked interstitial thickening, and the cut surface had a distinctly white color. At the apex there was a small nodule, which was completely encapsulated, and looked like a gummy tumor, as seen elsewhere in the body. The left lung was similarly but less extensively affected, though it contained no nodules. The spleen was enlarged and indurated. The right kidney was more than double its usual size. It represented under the

microscope the kidney in a state of parenchymatous change, with some intertubular thickening; vessels not affected. The left kidney had been almost obliterated by some process, either of a hydropneumothoracic character or suppurative; and in place of it was only a thin layer of renal tissue, embracing a small, saccular dilatation of the ureter, and also a mass of fibrous tissue embedded in fat. Liver was enlarged, cirrhotic, pigmented, and fatty; it showed signs of old perihepatitis, with several small cicatricial depressions; weight was seventy ounces. At one point in the pia mater there was a marked stellate thickening, as if a gumma at that point had been absorbed. The cerebral vessels showed marked atheromatous change.

#### A CASE OF DOUBLE OPTIC NEURITIS ACCOMPANIED BY CONSIDERABLE AMBLYOPIA: POSSIBLY CAUSED BY ARSENICAL POISONING.<sup>1</sup>

BY H. H. DERBY, M.D.

THE following case, both from the obscurity of its symptoms, its obstinate duration, and its ultimate improvement under peculiar circumstances, has seemed to me one of unusual interest, especially in view of the present legislative investigation, and to merit being reported.

Mr. R., aged twenty-six, a man of regular habits, and, with the exception of a chronic eczema, enjoying good health, was sent me by his physician, Dr. H. H. A. Beach, November 22, 1890. For ten days past he had noticed some obscuration of vision, as well as a slight blur on attempting to read. The eyes were externally normal. The ophthalmometer revealed no corneal astigmatism. Visual fields unimpaired. There was a trifling myopia in each eye, with a vision right of four-tenths, left of eight-tenths. Ophthalmoscopic examination showed nothing unusual except a minute hemorrhage at the edge of the right optic nerve, slightly encroaching on the disc.

December 2d, vision of the right eye had fallen to one-tenth. A careful ophthalmoscopic examination made after dilating the pupil, showed the hemorrhage to have disappeared and the fundus to be absolutely normal.

December 18th, there was a still further diminution of vision, it having fallen in the right eye to one-twenty-fifth, in the left to five-tenths. There was on each side slight optic neuritis, the nerves being a very little swollen, but with unobscured outlines; the vessels retaining their normal calibre. Much headache was experienced, the patient was obliged to give up the practice of his profession (the law) and was growing alarmed about his condition. He had observed that he could no longer read his own writing unless he used an extra amount of ink. I now put him on small doses of iodide of potash.

December 26th, vision right one-twentieth, left two-tenths, being a slight improvement in the right eye. On this side the swelling of the nerve was less, and its surface had taken on a decided pallor. The neuritis in the left eye was more marked, the disc being more swollen and its edge less defined.

January 1, 1891, vision had improved slightly, being now in right eye one-tenth, in left a little less than

<sup>1</sup> Read before the Boston Society for Medical Observation, April 6, 1891.

four-tenths. No ophthalmoscopic change. January 12th, there was an improvement of a single tenth in the left eye. The neuritis had abated and each disc had regained a normal appearance. But on the 19th, without visible change, the vision of the left eye had fallen off to three-tenths, that of the right remaining at one-tenth. For ten days past there had been a severe "hammer-like" pain in the head, but it had now disappeared.

January 22d, Dr. C. F. Folsom saw the case in consultation. In addition to what has previously been detailed nothing new was discovered. Dr. Folsom suggested the possible presence of a cerebral tumor, but was rather inclined to the theory of a subacute basal meningitis, unless an examination of the urine, which he suggested, should show the presence of lead or arsenic.

No lead was found, but Dr. Wood reported, January 31st, that the urine contained arsenic, not in large quantity, but in sufficient amount to prove the absorption of the poison from some source.

Mr. R. had moved into his present house in 1884. The library, in which he was in the habit of passing much of his time, had been papered in 1880. It was a room measuring thirteen by twenty-four feet in length and breadth, and nearly eleven feet in height. Around the top ran a paper frieze, thirteen and one-half inches in width. A specimen of this frieze is here presented. Mr. R. sent it to Mr. Durkee for analysis and I quote his report.

"The library paper submitted me to be tested by the usual method of arsenical quantitative analysis was found to contain a considerable amount of this poison. The sample furnished me held eight and forty-four one-hundredths grains of metallic arsenic to a square yard, equal to eleven and one-fourth grains of common arsenic. It is probable that a larger quantity could be obtained from new paper, as a portion of the material with which the surface is covered, becomes detached very easily, and no doubt a portion of the arsenic originally present had become separated, as the roll sent me had been repeatedly opened.

"The paper is thickly coated with a mixture of organic matter, and the arsenical pigment being rough and porous, seems to me peculiarly liable to cause arsenical poisoning by either the mechanical detachment of particles, or the favorable conditions for chemical action which it furnishes when on a wall exposed to heat, light and moisture."

During the present season Mr. R. had not used the library more than usual. The remaining members of the family, two ladies, had passed more time in the room than he and had experienced no ill effects.

The walls were stripped early in February. Steady improvement has since taken place. March 8th, the vision of the right eye was nearly five-tenths and of the left nearly seven-tenths. It is but fair to state that a slight improvement had been noted January 21st, before the removal of the paper. The change for the better has, however, now been continuous for a number of weeks, while the history of the case shows that previous gain had been slight and followed by relapse. The patient is himself conscious of a steady and uninterrupted improvement, both for far and near.

The field of vision has exhibited no scotoma, either for white or colors. This fact leaves the case one of simple optic neuritis, although the very slight palpable

alterations in the optic disc, together with the grave affection of vision, are more common in retro-bulbar neuritis, of which the scotoma is so integral a feature.

This case is principally interesting as regards its causation, and, although brief, seems to me to merit being reported. The usual predisposing factors of optic neuritis are all absent. Symptoms of brain disease fail entirely, syphilis is excluded, albuminuria, diabetes and lead-poisoning are all wanting. None of the writers on this subject allude to arsenical poisoning as a possible cause. It certainly seems that here there is a presumption in its favor.

## THE REPORT OF A CASE OF PHLEGMASIA DOLENS.

BY GEORGE E. THOMPSON, M.D.

In the evening of December 1, 1890, I was called to see Mrs. F., thirty years of age, a primipara, who up to the seventh month of her pregnancy, with the exception of slight nausea and vomiting, had not been afflicted by any of the numerous troubles peculiar to that condition. At this time, however, there was quite a gush of blood from the uterus, but by resting quietly in bed, at the end of forty-eight hours the flowing had stopped.

At the eighth month, four days before the date of my first visit, the hemorrhage returned again, and it had been so profuse during these four days that I found her in a very miserable condition. Her lips were pale; her pulse was 120 and weak; she complained of feeling faint, and was constantly calling for air which must have been partly due to the high temperature of her room, as after opening the windows she became greatly relieved. I will state here that she had been under the care of a midwife, but her husband becoming alarmed at her weakness called me in to take charge of the case. I was unable to make a thorough examination on account of the nervous condition of the woman, but considered that I had to deal with at least a low attachment of the placenta if not with placenta prævia itself. As the patient was having slight labor pains, and the loss of blood did not seem very great then, I tamponed the vagina with absorbent cotton wrung out in 1-1000 corrosive sublimate solution, thinking that the tampons would be sufficient to check the flowing, and at the same time from their irritant action produce stronger uterine contractions; and such was the result. After making her as comfortable as possible I left, telling her husband to call me when the pains became severe, but he, not wishing "to send too soon" as he expressed it, did not notify me until nine o'clock the following morning though her pains had been quite hard nearly the whole night.

Upon my arrival I found that the tampons had been forced out some hours before, that there had been no more hemorrhage, and as the os was fully dilated, I ruptured the membranes (which were bulging the perineum), and after suffering pain for half an hour longer, she gave birth to a fetus that had been dead for some time as the skin was macerated off in large patches all over his body.

The breasts easily dried up, and the patient did very well until December 10th (eight days after her delivery), when she began to have considerable pain

of a sharp, shooting character in the calf of the right leg. Linseed-meal poultices relieved the pain slightly, but opiates were required to produce sleep. The following day the ankle was slightly swollen, and two days later the foot and leg up to the knee were greatly enlarged, were of a shiny, white color, and were of a hard, tense feel. There was much tenderness over the course of the external saphenous vein, which could be felt as a cord rolling under the finger.

December 17th. There being but little pain remaining in the leg, I removed the poultices; and as the swelling had not diminished, after wrapping the limb in sheet-wadding, it was bandaged tightly from the toes to the knee. (I did not consider it necessary to extend the bandage farther up, as the thigh was only moderately swollen.) This bandage was tightened daily until the swelling disappeared in the mid dle of January.

Thinking that my patient was doing well, I did not see her again until December 21st, when I was sent for. She had, against orders, been up walking about

ful, hot or red, and had a doughy feel, I thought it to be simply an oedema of the part. This disappeared without treatment in about a week's time.

With the right leg the temperature did not run up to over 102.6° at any time that it was causing her trouble, but with the left leg on the evening of the 22d of December, it reached 105°, and the pulse was at its highest rate, 140. At this time the respirations were fifty a minute, and kept up above forty for the next four days, after which they gradually worked back to the normal. As she had no cough nor any rational or physical signs of heart or lung disease, while this rapid respiration lasted, I was very much afraid that she might be in danger from a pulmonary embolus or thrombus.

Throughout her sickness my patient took large quantities of liquid nourishment, though occasionally the morphine caused her to vomit. Her bowels were constipated, and were moved by an enema every two or three days.

January 4th. There being no pain whatever, and the left thigh being softer and somewhat smaller, the poultices which had been on until this time, were replaced by sheet-wadding and a bandage.

January 11th. Yesterday slight pain in both legs from walking too much, but resting in bed made them all right again to-day.

January 18th. Thirty-nine days from the commencement of the pain in the right leg, Mrs. F. is practically well again.

February 1st. She walked half a mile to my office without fatigue, and without causing any pain or discomfort in the legs.

This case was especially interesting to me on account of the difference between the two legs. In the right we had about all of the swelling below the knee, while in the left it was nearly all above the knee. In the right we had an easily felt, indurated saphenous vein, while in the left at no time was I able to detect any such induration of a vein.

The great loss of blood before confinement in addition to the usual puerperal condition of the blood together with septic absorption from some source are the reasons why my patient had such an experience with phlebitis in combination with thrombosis of the veins and lymphatics.

the room. I found her nearly wild with pain on the inner side of the left thigh. This pain was very severe for the following five days, and I had to inject morphine several times daily in order to keep her comfortable at all. During the next twenty-four hours this pain extended down into the calf of the leg, and she also had it in each buttock. For about a week at this time my patient was in a very unhappy state. The dorsal position was the most comfortable for her on account of the left leg; but the buttocks were so painful and tender that she felt a change of position was absolutely necessary, yet when the attempt was made it was found that the slightest motion increased the pain in the leg so that it was unbearable. The thigh became enormous in size, and remained so for two weeks before commencing to grow smaller at all. The leg below the knee was not greatly swollen. At no time could I detect any hard inflamed vein as in the right leg.

December 27th she called my attention to a new swelling, and I found the left side of the vulva enlarged to the size of my fist; but as it was not pain-

## Reports of Societies.

### BOSTON SOCIETY FOR MEDICAL OBSERVATION.

T. F. SHERMAN, M.D., SECRETARY.

REGULAR Meeting, Monday, April 6, 1891, DR. E. N. WHITTIER in the chair.

DR. GEORGE E. THOMPSON read a report of

#### A CASE OF PILEGNASIA DOLENS.<sup>1</sup>

DR. C. M. GREEN: I would like to ask the reader if he can tell about the temperature from the time the baby was born until he first noticed the condition of the leg.

DR. THOMPSON: I cannot, because I did not take it, as from the character of the pulse and feeling of the skin I thought she was free from fever.

<sup>1</sup> See page 604 of the Journal.

DR. GREEN: I understood the reader to say he attributed it to sepsis.

DR. THOMPSON: I suppose in almost every case where there is phlebitis there is some septic trouble.

DR. GREEN: It struck me that it was not a case of septic phlebitis. I suppose the majority of cases of phlegmasia dolens in childbed are due to sepsis, but I think there are cases not due to sepsis. It seems to me this is one. If it was due to sepsis, she would have manifested septic symptoms earlier in her convalescence, it seems to me. I have had two cases in which phlegmasia dolens developed considerably later than this, where I felt very sure it could not be due to sepsis, because the patient had made a perfect convalescence without rise of temperature. It seems to me that while we ought not to be any less careful in regard to septic precautions, we may comfort ourselves occasionally, in cases of phlegmasia, in the belief that phlegmasia does not necessarily proceed from sepsis. Certainly in this case I should think the woman had every right to it from the general condition. She had lost a good deal of blood before labor began, and that with poor general condition I should think would be a good reason why she might have thrombosis and phlebitis and phlegmasia.

DR. H. DERRY read a paper on

A CASE OF AMBLYOPIA WITH SLIGHT OPTIC NEURITIS, POSSIBLY CONNECTED WITH ARSENICAL POISONING.<sup>2</sup>

DR. MIXTER: If I may speak in regard to the general subject of arsenical poisoning, there is one point which has been very thoroughly ventilated of late, and that is the susceptibility of one member of a family and the exemption from symptoms of other members in the same family and under the same circumstances. I think that any one who has had experience with cases of arsenical poisoning, either in their own families or in those of their parents, will have noticed that fact as being a very marked one in a great many cases, that certain members of the family will be very susceptible to the influence of arsenic, and that the symptoms will be marked whenever new articles of furniture are brought into the room which are covered with coverings containing arsenic. That has certainly been one of the marked features in cases I have seen, and it accounts I think largely for the idea that this is a fall, and that people who claim to have been poisoned by arsenic are simply afraid that they have been. It seems to me that it is beyond dispute that one member of a family may be seriously affected and others entirely exempt. It is simply a case of idiosyncrasy, and should not be taken into account, as has been done by certain people who have been interested, or rather not interested, in the late movement against arsenical wall-papers and fabrics.

DR. HODGES: I should like to ask how he accounts for the fact that this gentleman lived in the house for ten years and had not been previously affected by arsenic, for there was presumably more arsenic in the paper when it was put on than later.

DR. MIXTER: As I understand it, arsenic is a cumulative poison. We know we can give Fowler's solution a considerable time, and then it may have unpleasant effects. We know it takes a very long time to eliminate arsenic. Arsenic has been found in the urine, I believe, for months after all causes were re-

moved, and as it is being absorbed all the time, it is possible it may get to a point where some trouble is caused.

DR. J. J. PUTNAM: It is certainly true that cases of neuritis for which no ready cause can be found present themselves every now and then; and it is very interesting to have a new possible cause suggested. It is also important to be reminded that in the history of undoubted arsenical poisoning, such as occurs from the administration of arsenic for prolonged periods, and where the health is not otherwise affected, single nerves, special nerves, are singled out to become inflamed. The most striking example of this is perhaps the occurrence of herpes zoster, which has been noted a good many times in cases of arsenical poisoning, especially among children who have been given arsenic for therapeutic reasons. Neuralgias and neuritis confined to single nerves have also been observed.

The whole subject is a mysterious one; and although I think almost all the physicians in this city have been persuaded by the great mass of special evidence that arsenical poisoning does occur in consequence of the absorption of limited quantities of arsenic from fabrics and wall-papers, and also perhaps in other ways, still the medical community is now divided to some extent into those who take a conservative position and those who take a more positive position. I do not see why the burden of proof should be with one of these two parties more than the other. There does not seem to be any particular reason why we should not all welcome the possibility of the fact that we have discovered a new cause of various symptoms that we had hitherto attributed to no cause at all perhaps. The circumstantial evidence is very strong; and we should recognize that in the first place we have typical cases of arsenical poisoning, as clear as those which occur in consequence of toxicological doses of arsenic, and a much larger number of milder cases or cases where some particular part of the body is singled out to show the effects of the poison.

With regard to the question why these cases occur in persons who have not shown signs until a long period of exposure, it seems to me that the reason suggested by Dr. Mixter is the important one. We all speak of the smallness of the dose taken in from fabrics and wall-paper, but the possibility that arsenic is a cumulative poison has not been fully recognized. That has been known in reference to lead, but arsenic has been supposed to be eliminated very quickly. This is now proved to be not the case, as a rule. The number of cases is quite large where arsenic has been given for therapeutic purposes for a long time without the slightest harm and yet where finally more or less violent symptoms of poisoning have broken out.

DR. C. P. PUTNAM: I should like to add a few words to what Dr. Mixter has said, not but that he might have said the same thing himself if it had occurred to him. All the peculiarities of the infection of arsenic are observed in the zymotic diseases. We see constantly people who have grown to adult life without having scarlet fever, though often exposed to it. It is not uncommon when a large number of children are exposed to scarlet fever that only a small number take it. The same is true of the other exanthemata. Certain members of a community do not at a given time supply the fertile field which is necessary for the disease to take root. Then the poison of ivy, which is resisted by some people a very long time, but when

<sup>2</sup> See page 602 of the Journal.

they have once been poisoned, they are very easily poisoned afterwards. The same thing is observed in the case of tea. There can be no question that people who are once poisoned by it often continue to be affected by even very small quantities, and do not get over it until they have made up their minds to give up the tea altogether. I have mentioned these things because it is commonly said, that the danger of arsenic is much exaggerated, and that it cannot have the effects claimed for it because it acts in the peculiar ways, which are in fact peculiar to all poisons.

DR. PUTNAM showed a specimen of

#### TUMOR OF THE BRAIN,

from a patient who died in the Massachusetts General Hospital in the service of Dr. G. G. Tarbell.

The patient's only symptoms consisted in headache and double optic neuritis for a long time, and then paralysis was added. The diagnosis was finally made as to the character of the tumor with a good deal of probability, because sarcoma was discovered in other parts of the body. The tumor lies just in front of the area which is concerned in acute vision (the cuneus), and directly behind the area which is concerned in the motion of the trunk and limbs, on the mesial surface of the brain, so that, as a matter of fact, it apparently just avoided destroying either of these important regions of the cortex. The patient was a young man about thirty.

DR. FITZ: The point in reference to the diagnosis of the nature of the tumor is important. The mass of cerebral tumor apparently is of much longer duration than the nodule. In case of sarcoma of the brain and skin, the primary tumor is much more likely to be in the skin than brain, and they may represent different structures; that in the brain may be of some other variety. Dr. Putnam was very modest in not calling attention to the fact that the discovery of the nodule in the skin led to the accurate diagnosis of the cerebral tumor.

DR. AYER reported a case of

#### VARICELLA IN AN ADULT.

Upon the first visit there was slight fever; nothing special noticed from the symptoms. The next day the temperature was 102.5°. Acne spots appeared on the face, and several on the chest, which looked like those on the face. Two or three had a little fluid very near the apex. I sent him home, and told him to go to bed. The next day there was no question about the case being varicella. The vesicles were not well marked. They were on the skin rather than in the skin. He had never been vaccinated. That evening I found that two which appeared in the morning had become vesicular during the day, establishing the diagnosis beyond a question. It is rare to see varicella in adults. I do not think I ever saw a case before, although I have heard of them. It seemed decidedly more like acne.

DR. C. P. PUTNAM: I should like to relate a case where varicella was carried on the clothing of a third person, an accident that is very uncommon. The persons concerned were a grandmother, a daughter and a daughter's child. The grandmother and daughter lived in towns four or five miles apart. The grandmother took the child home with her from Groton to Pepperell in the steam-cars, and two weeks after that the child had chicken-pox. There was no other case

in Pepperell. The grandmother went back to Groton just about the time the child had the eruption, and in two weeks from that time the daughter had the disease. There was no other case of chicken-pox in Groton, so it seemed plain that the first case was taken in the cars, and the second one was taken from the first by the clothing of a third.

DR. J. J. PUTNAM spoke of

#### CASES OF PAIN (ON WALKING) IN THE SOLE OF THE FOOT, RADIATING OUT TO CERTAIN TOES.

In the cases I have seen the most common position for the tenderness has been the space between the third and fourth toes, and after a time the neighboring parts and the distribution of the digital nerves. In the cases I have seen, also, the foot after a time aches, and the leg, and the person is in great distress. I had not very long ago a young woman come to me who was suffering excessively in that way. She was in very acute distress, and the relief was found by carefully studying out the position of the tenderness and relieving it by cutting a corresponding hole in the inner sole of a new boot which was made large and broad.

I believe that this has been recognized and written about, and it is said that the digital nerve in this position, and sometimes between the other toes, gets caught between the metatarsal bones. I do not think it is perhaps as fully understood as it should be, nor the ease with which the remedy can be applied. The method I have adopted is to ink the spot on the foot that is tender and get the patient to put the foot inside the sole which is slightly moistened, and cut out a long oblong slit running considerably forward and back of the tender part.

#### MASSACHUSETTS MEDICAL SOCIETY. THE ONE HUNDRED AND TENTH ANNUAL MEETING.

BOSTON, JUNE 9 AND 10, 1891.

FIRST DAY.—TUESDAY, JUNE 9TH.

#### THE MASSACHUSETTS GENERAL HOSPITAL.

A LARGE delegation of the Society attended the operations and visited the wards, where many interesting cases were exhibited.

DR. BEACH amputated the breast of a woman for cancer, and operated for hare-lip, the patient an infant of eight months old. He also amputated the thigh of a man who had suffered for twenty-five years from chronic disease of the knee-joint, tapped a large hydrocele, and excised nearly the whole shaft of the tibia, the bone having become necrosed from an extensive attack of diffuse suppurative periostitis.

Through the courtesy of Dr. William L. Richardson of the Boston Lying-in Asylum, he was enabled to show an infant born with an imperforate rectum, whom he had seen in consultation with Dr. Bates, the house-officer of that institution. There had been a history of a slight discharge of meconium soon after the birth of the child, but a most careful inspection failed to disclose any opening leading from the anus into the bowel. The anus permitted the entrance of the little finger into a small cul-de-sac. The abdomen was firm and very much distended, and the stomach rejected all nourishment. No impulse could be felt in the rudimentary rectum when the child cried, but upon the

insertion of an ear speculum a very slight protrusion was observed in front of the sacrum. Dr. Beach inserted a trocar and canula at the point described, giving exit to an abundance of meconium. Dr. Beach, in presenting the case, said that the child was gaining daily, taking a good share of nutrition, and is having regular and natural discharges from the bowels. Dr. Beach remarked that before operating he had concluded to puncture once only, and if that had proved unsuccessful, to do a laparotomy and determine the exact location of the intestine loaded with meconium. Having made that point clear, the next step would be to puncture from the outside in the direction of the bowel, or be otherwise guided by such complications as should present themselves. The patient was taken to the aseptic ward for that purpose, but the success of the puncture made the operation unnecessary. Curiously enough, a second case entered the hospital two days afterward, in charge of Dr. Conant, then substituting for Dr. Homans. In the latter case the skin of the perineum was unbroken by the slightest vestige of an anus. Dr. Beach saw this case in consultation with Dr. Conant, and advised a careful dissection on the central line in the direction of the rectum, and should any impulse be felt, to puncture once, and if no meconium followed, to do a laparotomy, as he had planned in the first case related. Dr. Conant had skillfully followed the plan and was successful in finding the distended intestine leading down to a fibrous diaphragm stretching across the pelvis from one side to the other. A trocar and canula were now inserted in the ischio-rectal wound already described, and pushed carefully through the fibrous diaphragm into the cavity of the intestine, its direction having been guided by the finger of the operator in the abdominal cavity. Upon withdrawing the trocar, a large amount of meconium followed through the canula, which was retained in position until the wound had become nearly healed. The abdominal wound healed promptly, and the child eats, gains in weight, and has natural movements of the bowels without discomfort, and is the youngest patient (seventy-four hours old) upon whom laparotomy has been performed in the Massachusetts General Hospital.

Among the interesting cases on exhibition in Dr. Beach's wards, was one of recovery without a symptom of compression or concussion from a compound fracture of the skull on the median line, three and one-half inches above the glabella. The man, while lying upon a railroad track, had been struck by the cow-catcher of an engine, which pulverized the bone and tore a large opening into the longitudinal sinus, causing a considerable hemorrhage. He also showed a case of extensive epithelial cancer, involving the whole side of the face and exposing the nasal fossae, the pharynx and buccal cavity. The disease had begun to encroach upon the orbital cavity. Dr. Beach also presented the following cases: A serviceable stump following an amputation at the ankle-joint, by the method of Roux; a case of complete rupture of the urethra in a boy, from a fall astride the edge of a barrel (immediate perineal section was performed, a large amount of clot turned out of the distended perineum, and a catheter was tied in place to maintain a continuous drainage from the bladder); recovery from ovariotomy, cyst and contents weighing thirteen pounds; cases exemplifying an improved method of extension in fractures of the thigh; a sarcoma of the thigh, involving the

femoral artery; recovery from double fracture of the femur, one compound; recovery from the removal of a large hamatocoele, the tumor measuring eighteen inches across its anterior face, and the sac three-quarters of an inch thick, the patient being a subject of extensive heart malformation (congenital); case of tracheotomy for foreign body in the bronchus; one of extrophy of the bladder; and one recovering from compound fracture of the patella.

Dr. HOMANS amputated the thigh of a man with chronic tuberculous disease of the knee-joint. He also operated upon a case of epithelial cancer of the tongue complicated by suppurating glands of the neck, removed the fragments of bone from a compound fracture of the ankle-joint, and dressed the wound. Among the interesting cases shown by Dr. Homans was one of sub-dural hemorrhage from accident. The condition was diagnosed by Dr. Walton, and the operation successfully performed by Dr. Homans. He also exhibited a comminuted compound fracture of the patella, which had been successfully treated by wiring.

Dr. WARREN exhibited a patient slowly recovering from an amputation of the hip-joint for chronic tuberculous disease.

Dr. PORTER showed the photographs and described the operations in a case where he had removed enormous hypertrophied breasts. He also showed a patient from whom he had successfully removed the appendix in the intervals between recurring attacks of inflammation.

Dr. CABOT performed a laparotomy for appendicitis with general peritonitis. There also existed the complication of suppurating inguinal glands.

Dr. DURAND, a former house-officer of the hospital, displayed an ingenious and satisfactory method of irrigation.

#### MEETINGS OF SECTIONS.<sup>1</sup>

At two o'clock the Sections in Medicine, Surgery and Obstetrics and Gynecology met in different halls of the Massachusetts Charitable Mechanics Association Building on Huntington Avenue.

#### THE SHATTUCK LECTURE<sup>1</sup>

was delivered in the evening at eight o'clock in Cotton Hall, by Edward Cowles, M.D., of Somerville.

#### THE COUNCILLORS' MEETING

was held at the Medical Library, 19 Boylston Place at eleven o'clock, A. M.

#### EXHIBIT.

On Tuesday and Wednesday there was an Exhibit in the Main Hall of the Mechanics Building. It was somewhat more comprehensive than heretofore, and was largely visited by the members. A conspicuous place at the right of the entrance was given to surgical instruments and appliances, and many of the more modern inventions and improvements upon the older instruments were shown by the various local firms.

A large and interesting assortment of modern orthopedic appliances from the Children's Hospital offered good evidence of the activity and advancement of this branch of medicine, and added greatly to the interest of the exhibit. It was much regretted that a prominent electrical company, who had planned an extended

<sup>1</sup> A report will be published in a later issue.

exhibition of electrical apparatus, were unable to appear on account of delay in the arrival of their goods. There was the usual large attendance of druggists, with their supplies of pharmaceutical preparations, together with exhibits of oxygen, mineral waters and Russian koumiss. Four firms of carriage-makers displayed various styles of physicians' carriages and carts, which attracted considerable interest. Among the other exhibits may be mentioned several new devices for operating-tables and sofas, typewriters, bicycles and other appliances that are coming into increased use among the members of the profession. A larger representation of hygienic and sanitary apparatus might be desired, and it is hoped that it will be possible at another meeting to introduce some new features of interest in this direction.

## SECOND DAY.—WEDNESDAY, JUNE 10TH.

## THE BUSINESS MEETING

was held in Cotillon Hall, Mechanics Building, at nine o'clock. The meeting was called to order by the President, A. H. Johnson, M.D., of Salem.

The Treasurer's report showed that the receipts for the year had been \$12,198.69; expenditures, \$10,173.63; balance, \$2,725.06.

The present number of members is 1,733. During the year 116 new members have been admitted, and 39 members have died.

A communication was received from the Suffolk District Medical Society, suggesting the appointment of a committee in regard to an asylum for adult chronic epileptics. Dr. W. N. Bullard, Dr. G. F. Jelly, Dr. A. R. Moulton, Dr. G. Brown and Dr. L. W. Baker were appointed to present a bill to the Legislature in regard to the matter.

Papers were read by Dr. Paul Thorndike, of Boston, on "Catheter Fever"; by Dr. Homer Gage, of Worcester, on "A Case of Nephrectomy"; by Dr. F. H. Williams, of Boston, on "How shall we Nourish in Acute Disease."

Representatives from other State societies were invited to the platform and introduced, as follows: Dr. E. D. Hall, of Meriden, Conn.; Dr. E. M. Brown, of Sheldon, Vt.; Dr. J. W. Staples, of Franklin Falls, N. H.; Dr. G. P. Conn, of Concord, N. H.; Dr. W. T. Smith, of Hanover, N. H.; Dr. T. S. Dawes, of New York. They responded with brief speeches.

The officers of the Society for the ensuing year are: Amos H. Johnson, Salem, President; J. J. B. Vermeyne, New Bedford, Vice-President; Frank W. Draper, Boston, Treasurer; Charles W. Swan, Boston, Corresponding Secretary; Francis W. Goss, Roxbury, Recording Secretary; Edwin H. Brigham, Boston, Librarian; Frank W. Draper, Boston, Orator; E. H. Bradford, Boston, Anniversary Chairman. The Standing Committees are: of Arrangements, R. W. Lovett, J. Homans, 2nd, J. T. Bowen, F. M. Briggs, H. Jackson, J. C. Munro; on Publications, G. C. Shattuck, B. E. Cotting, O. F. Wadsworth; on Membership and Finances, F. Minot, B. S. Shaw, J. Stedman, E. G. Cutler, L. R. Stone; to Procure Scientific Papers, H. P. Walcott, F. H. Zabriskie, E. H. Bradford, L. Wheeler, S. B. Woodward, C. W. Townsend; on Ethics and Discipline, G. J. Townsend, G. E. Francis, F. C. Shattuck, C. G. Carleton, E. Cowles; on Medical Diplomas, E. J. Forster, F. H. Hooper, H. E. Marion.

At twelve o'clock the

ANNUAL DISCOURSE<sup>2</sup>

was delivered by DR. JAMES B. BREWSTER, of Plymouth.

## THE DINNER.

The procession was then formed, and the Fellows, in order of seniority, marched to the Grand Hall, where dinner was served, music for the occasion being provided by the Germania Orchestra. The officers and invited guests occupied the platform, while nearly nine hundred Fellows were seated at the several long tables on the floor. At the close of the dinner, the Anniversary Chairman, DR. THEODORE F. BRECK, of Springfield, called the assembly to order, and spoke as follows:

*Mr. President, and Fellows of the Massachusetts Medical Society:*—The fulness of my heart to you all! My congratulations to all the good Fellows who have gathered here on this One Hundred and Tenth Anniversary of our Society! my felicitations on the good cheer we have partaken of! my welcome to that post-prandial feast where the French *chef* makes way for Apollo and the Muses, and creature comforts yield place to the delicacies of the human intellect.

How delicious indeed are these festal occasions,  
When science unites with soup, fish and meat,  
And we pass from the wards of expert operations  
To a *menu française* and plenty to eat!

To learn of Koch's lymph, *la grippe* and hypnosis,  
Of the latest and best in the medical line;  
And after the "tips" on diag- and prognosis,  
To sit at this board and fraternally dine!

To hear of ourselves and our noble profession,  
Of a life that is work and a way that is rough,  
And then to march forth, in ordered procession,  
To *filet de soles* and *coquilles aux truffes*!

To feast in this hall, where music symphonie  
Gives a tone to the soups and a taste to the roasts,  
Where Wagnerian strains prove a capital tonic  
To those who respond to the post-dinner toasts!

The post-dinner toasts! we hail them with pleasure.  
They nobly accord with Havana cigars.  
Of wisdom and wit we'll have a full measure,  
And finish our feast with a trip 'mong the stars.

As I look around upon this vast assemblage, and see such a noble body of men brought together for the purpose of advancing the science of medicine and surgery, my heart fills with joy and pride to think that this Commonwealth can boast of such an organization. What a power here exists, what great thoughts and ideas are constantly being developed, and what advancement is yearly made in behalf of mankind! It is by frequent intercourse and the interchange of ideas, that we are so far advanced in our profession.

But our Society is destined to become larger in membership, and we trust still further advanced in all that pertains to the relief of suffering humanity. The advantages which our schools give to the medical student to-day compel a higher class of men to enter our ranks, who by their skill and learning will raise the standard of medicine to that point where the medical profession may well be called the noblest of all.

May our Society still continue to grow and become prosperous! may it wield a power over the public in general to the extent that its high standard will be felt throughout this great Commonwealth!

## THE MASSACHUSETTS MEDICAL SOCIETY.

The first sentiment of this occasion — one to which every heart will respond, though but one tongue voice — is our own Massachusetts Medical Society: from the mouth of him who has ever had its interests uppermost in his heart, our worthy President, Dr. A. H. Johnson, of Salem.

DR. JOHNSON spoke as follows:

An adequate response for the Massachusetts Medical Society is to be found not in my words, but in the eloquent suggestiveness of this gathering of its members. To the pessimist, the prosperity of this vigorous Society of more than 1,700 doctors, would solely call to mind diseases, sufferings, drugs and surgery. Yet all vocations in life have their higher as well as their lower relations. Flowers grow from man's manipulations of the repellant decay from which they spring; but thoughts of a florist should not chiefly suggest his heaps of compost. Likewise this body of physicians most justly reminds us, not of the sicknesses and wounds they heal, large and beneficent as such services are, but of the fairer, larger product of their sanitary knowledge and councils, in the greater happiness they have made attainable in all the relations of life. These nine hundred representatives of our Society most impressively suggest the character and magnitude of the labors out of which they have come, and the spirit with which those labors have been performed. Their presence reminds us of their fidelity, as a body, to much obscure, sometimes revolting, too often unremunerated, although life-giving service, as well as of public spirited acts, and deeds conspicuously skilful, which have brought well-earned honor and wealth to not a few.

Nor can one fail to reflect upon the exacting thoroughness of the training to-day required to fit them for their duties. In the days when the wisdom of doctors was gauged by the size of their wigs and the pose of their canes, Oliver Goldsmith, we are told, in order to enter upon the practice of physic, donned the professional wig, and a second-hand suit of rusty black velvet, with a patch on the left breast, which he adroitly covered with his three cornered hat, all the while anxious since the courtesy of friends compelled him to defend it from removal. Should one enter upon the practice of medicine to-day with the garb of medical learning of even one generation ago, although it would cover much otherwise naked ignorance, it would require more than one hat to cover its deficiencies, and John B. Gough's three-handed men to hold them; men who always come with a right hand, a left hand, and a little behind hand.

Occasionally, in the newspapers we read of this Society, as representing the "old school" of medicine. The term misleads. Old it is, in devotion to rational methods of investigation and treatment; old, in hostility to notional, pseudo-scientific teachings; old, in purpose promptly to adapt the latest scientific knowledge to relieve suffering and prolong life; old, as processes of evolution are old; old, as conformity to a primeval, ever-enduring system of nature compels one to be; old, as the sciences of chemistry and of astronomy are old; old, because "art is long, and time is fleeting." In this sense, the principles which guide this Society are honed as the laws of nature, yet like them have the vitality of perennial youth. We are members of an "old school" not as adherents to any

dogmas controlling medical practice, otherwise than as life-long, and for all time supporters of the principles of philanthropy, of professional honor, and of scientific honesty. Dogmas founded upon speculations as a basis for medical practice were cast aside generations ago, as the chrysalis out of which the minds of medical men, in common with modern students in every calling, have sprung into a new realm bounded only by the universe itself.
